La Dra. Carolina Mallol Duque, profesora titular de Prehistoria del Departamento de Geografía e Historia (UDI de Arqueología, Prehistoria e Historia Antigua) de la Universidad de La Laguna

CERTIFICA:

Que la Tesis Doctoral titulada “Investigating microscopic and molecular organic matter to explore the role of Neanderthal social and cultural evolution at a regional scale” presentada por Rory Connolly ha sido realizada bajo mi dirección y reúne las condiciones de calidad y rigor científico para que pueda ser presentada y defendida ante la comisión nombrada al efecto.

Y para que así conste y surta los efectos oportunos, firmo el presente certificado en

San Cristóbal de La Laguna, Febrero de 2021.

**INVESTIGATING MICROSCOPIC AND MOLECULAR ORGANIC MATTER TO
EXPLORE THE ROLE OF CLIMATE IN NEANDERTHAL SOCIAL AND
CULTURAL EVOLUTION AT A REGIONAL SCALE**

ABSTRACT

The role of climate change is a recurrent theme in debates concerning the replacement of Neanderthals by anatomically modern humans across Europe and western Asia. The Iberian Peninsula is widely regarded as a key geographic location for understanding this process, owing to the apparent late survival of Neanderthal populations along its southern and western fringes. Despite this, relatively few long-term terrestrial palaeoclimate records are available against which hypotheses concerning climatic and ecological factors can be tested. Global climatic datasets from analyses of ice-cores obtained from the polar regions have provided a framework for understanding broad fluctuations in climate over geological timescales. At a higher scale of resolution, analysis of speleothems and palynological studies of marine cores off the Atlantic and Mediterranean coasts provide our most complete records of Pleistocene conditions throughout Iberia. Nevertheless, the extent to which these records accurately reflect regional and local terrestrial conditions in the areas inhabited by Neanderthal groups remains unclear. The persistence of locally favourable conditions in certain parts of the peninsula during periods of wider global climatic downturn cannot be discounted, and relatively few site-specific palaeoecological studies from human occupation contexts have been carried out. This presents a challenge for understanding long-term human-environment dynamics and the processes which drove the Middle to Upper Paleolithic transition.

Compound-specific isotope analyses of sedimentary organic compounds, particularly hydrocarbons derived from fossil leaf waxes (*n*-alkanes), have recently emerged as a powerful palaeoclimate proxy for reconstructing palaeohydrological (hydrogen isotope) and

palaeoecological (carbon isotope) conditions at a high spatial and temporal resolution. This technique has been successfully applied in a wide range of terrestrial environments, however, has rarely been utilised in archaeological contexts. Here we combine compound-specific carbon and hydrogen isotope analysis of sedimentary *n*-alkanes with archaeological soil micromorphology, a well-established geoarchaeological method, to better understand the sedimentary context of the target organic compounds and any potential biases which might arise due to anthropogenic activity or post-depositional processes. We investigate palaeoenvironmental conditions at the Middle Palaeolithic sites of Abric del Pastor (MIS 5/4) and El Salt (MIS 3) in Alcoy, Eastern Iberia, in combination with traditional palaeoenvironmental proxies employed in archaeological research, including charcoal, microvertebrates, macro-faunal remains and pollen. In addition, an experimental study has been carried out to assess the degree of thermal alteration on hydrogen isotope signatures of different plant organs of *Celtis australis*, a common anthropogenic fuel source at the study sites. Our results reveal the strengths of integrated microscopic and molecular approaches to address archaeological questions, highlight new avenues for future research, and add new levels of detail to our understanding of the regional environmental variability that framed the disappearance of Neanderthal populations in Eastern Iberia.

**INVESTIGAR LA MATERIA ORGÁNICA MICROSCÓPICA Y MOLECULAR PARA
EXPLORAR EL PAPEL DEL CLIMA EN LA EVOLUCIÓN SOCIAL Y CULTURAL
DE LOS NEANDERTALES A ESCALA REGIONAL**

RESUMEN

El rol de la variabilidad climática es un tema recurrente en las discusiones que rodean la sustitución de los neandertales por los humanos modernos en toda Europa y Asia occidental. La Península Ibérica se considera un lugar geográfico clave para entender este proceso, debido a la aparente pervivencia de las poblaciones neandertales en las regiones meridionales y occidentales de su territorio. A pesar de ello, se dispone de relativamente pocos registros paleoclimáticos terrestres lo suficientemente amplios para contrastar las hipótesis existentes sobre el rol de factores climáticos y ecológicos. Los análisis de las sondas de hielo de las regiones polares han aportado datos esenciales para construir modelos climáticos globales que abarcan escalas de tiempo geológicas. Los estudios palinológicos regionales de las sondas marinas de las costas atlánticas y mediterráneas son los registros paleoclimáticos pleistocénicos más completos para el estudio del ámbito ibérico. Sin embargo, aún no está claro hasta qué punto estos registros reflejan con exactitud las condiciones terrestres regionales y locales. No se puede descartar la persistencia de condiciones favorables a nivel local durante los periodos de enfriamiento global, y se han llevado a cabo relativamente pocos estudios paleoecológicos específicos de los contextos de ocupación humana correspondientes. Esto supone un reto para entender la dinámica sociedad-clima a largo plazo y durante la transición del Paleolítico Medio al Superior.

El análisis de isótopos específicos de compuestos orgánicos sedimentarios, concretamente de hidrocarburos derivados de ceras de hojas fósiles (*n*-alcanos), ha surgido recientemente como proxy ambiental alternativo que facilita la reconstrucción de las

condiciones paleohidrológicas (isótopos de hidrógeno) y paleoecológicas (isótopos de carbono) con una alta resolución espacial y temporal. Esta técnica ha sido aplicada con éxito en una amplia gama de entornos terrestres, pero rara vez se ha utilizado en contextos arqueológicos. En esta tesis, combinamos el análisis de los isótopos de carbono e hidrógeno específicos de los *n*-alcanos sedimentarios con la micromorfología de suelos arqueológicos, técnica fundamental para caracterizar el contexto sedimentario de los compuestos orgánicos objeto de estudio y así detectar cualquier posible sesgo antrópico o natural, como la biodegradación. Aplicamos estas técnicas para investigar las condiciones ambientales en los yacimientos del Paleolítico Medio de Abric del Pastor (MIS 5/4) y El Salt (MIS 3) en Alcoy, Iberia oriental, en combinación con proxies paleoambientales tradicionalmente empleados en estudios arqueológicos: el carbón vegetal, los restos de macro y microvertebrados y el polen. Además, se realizó un estudio experimental para evaluar la influencia de la alteración térmica en las huellas isotópicas de hidrógeno en diferentes partes anatómicas de *Celtis australis*. Nuestros resultados ponen de manifiesto el gran potencial de la aplicación integrada de técnicas microscópicas y moleculares para la reconstrucción paleoambiental y contribuyen un aumento en el grado de detalle de los datos paleoambientales actuales de cara a nuestra comprensión de la variabilidad ambiental regional existente durante el periodo de desaparición de las poblaciones neandertales de Iberia oriental.

Acknowledgements

I am extremely grateful to many people for all the support I have received throughout the course of this research. I owe a great debt of gratitude to my supervisor, **Dr Carolina Mallol**, for her guidance and encouragement over the last four years. Sincere thanks also go to all of the members of PALEOCHAR and AMBI Lab for their constant help and support throughout, as well as for creating an excellent research atmosphere to conduct this work. I must extend a very special thank you in particular to **Dr Antonio V. Herrera-Herrera** for his continual guidance, help getting to grips working with organic biomolecules, and his constant availability for technical support.

Thank you to all of my colleagues and **co-authors** who have contributed their analyses to the case studies included here and helped to teach me the value of truly interdisciplinary and collaborative research. Access to El Salt and Abric del Pastor and a great deal assistance were provided by **Dr Cristo M. Hernández** and **Prof Bertila Galván**. I am also grateful to all of the students and specialists who have dedicated their time and hard work to the excavation campaigns over the years, without which this research would not have been possible.

Thank you to **Dr Glenn Lambrecht** and **Lucia Leierer** for their friendship and fruitful discussions on topics related to the contents of this thesis. Very special thanks are also reserved for **Dr Marion Dowd**, **Dr James Bonsall**, **Sam Moore**, **Chris Read**, **Dr Fiona Beglane**, and **Dr Shirley Markley** at the Institute of Technology Sligo, all of whom have been a great source of encouragement and inspiration throughout the years.

I am deeply grateful to my girlfriend, **Alessia Ronchi**, for her enduring support, encouragement, reassurance, and infinite patience during the work for this thesis. Thank you also to my parents and friends who are always available and willing to help in any way they can.

Finally, this research was supported by the **European Research Council (ERC)**, **Spanish Ministry of Science, Innovation and Universities** and the **Government of Valencia Cultural Heritage Department**, to whom I am very thankful.

Chapter 1: Introduction

1.1. Neanderthal demise and the Middle to Upper Palaeolithic Transition

The disappearance of Neanderthals approximately 38 kya (Higham et al., 2014) and their subsequent replacement by anatomically modern humans (AMH) coincides with a significant cultural and technological shift in the archaeological record, commonly referred to as the Middle to Upper Palaeolithic transition (MUPT). Despite constituting one of the richest and most well-studied archaeological and palaeontological records in the world, built through more than a century of focused research throughout Europe and western Asia, much debate still surrounds the nature and timing of the major biological and cultural changes that define the MUPT (Roebroeks, 2008; Blockley et al., 2008; Galván et al., 2014; Higham et al., 2014; Hublin, 2015; Greenbaum et al., 2018; Mihailović, 2019).

Neanderthals and AMH diverged from a common ancestor between 550 - 765 kya (Prüfer et al., 2014). At present, the earliest secure dates for Neanderthal remains suggest that the species emerged approximately 400 kya, with a geographic distribution throughout much of Europe and western Asia. Genetic evidence demonstrates that interactions between Neanderthals and AMH, perhaps occurring as early as 100 kya in the region around the Levant, resulted in multiple episodes of genetic introgression and hybridisation (Sankararaman et al., 2014; Kuhlwilm et al., 2016; McCoy et al., 2017; Villanea and Schraiber, 2019; Price, 2020). This corresponds with archaeological and palaeontological evidence which demonstrates some degree of overlap in the geographic range of both Neanderthals and AMH for as much as 15,000 years in the Levant and perhaps a few thousand years in Western Europe (i.e. contemporaneous habitation or coexistence within a region, though not necessarily overlapping or involving a high degree of contact at the local scale) (Shea, 2003; Gravina et al., 2005; Nigst et al., 2014). Archaeologically, the MUPT is expressed as a diachronic and regionally variable

succession of distinct stone tool industries (d'Errico et al., 1998; Bocquet-Appel and Demars, 2000; Conard, 2011; Welker et al., 2016; Marín-Arroyo et al., 2018; Nigst, 2019). In Europe, incoming AMH groups, associated with Early Upper Palaeolithic (EUP) industries, arrived by at least 45-43 kya, eventually replacing the Mousterian industries associated with Neanderthals (Hublin, 2015; Roberts and Bricher, 2018). However, the authorship of certain transitional industries which have characteristics similar to both Mousterian and EUP assemblages remain the subject of ongoing debate (Welker et al., 2016; Villa et al., 2018)). There is disagreement as to the extent of the interaction, acculturation and genetic exchange which occurred between Neanderthals and AMH, however, what is clear is that by approximately 38 kya, Neanderthals had disappeared from the European archaeological record and the regions they formerly occupied came to be inhabited by AMH (Higham et al., 2014).

The complex spatiotemporal patterning involved in this process of cultural and biological replacement has led to numerous, often competing, hypotheses being put forward to explain the demographic collapse of Neanderthal populations. These largely fall into two broad categories, though they are not mutually exclusive. The first of these attributes Neanderthal demise to some form of direct or indirect competition with incoming AMH groups. This includes various models of competitive exclusion (Banks et al., 2008; Klein, 2009; Gilpin et al., 2016), dietary differences (Hockett and Haws, 2005; Richards and Trinkaus, 2009), disadvantageous biological or behavioural capacities (Dibble et al., 2018; Goldfield et al., 2018), differences in life history (Trinkaus, 1995, 2011), cognitive inferiority (Mellars and Stringer, 1989; Klein, 2003), and selectively neutral species drift (Kolodny and Feldman, 2017). The second broad category highlights environmental factors, including viral disease (Underdown, 2008; Wolff and Greenwood, 2010) and significant volcanic eruptions (Golovanova et al., 2010; Morley, 2012; Fedele et al., 2016), but primarily focuses on the role

of climate change (d'Errico and Sánchez Goñi, 2003; Jiménez-Espejo et al., 2007; Finlayson and Carrión, 2007). It is the latter with which this thesis is concerned.

1.2. Neanderthals and climate in the Iberian Peninsula

Climatic and environmentally deterministic explanations for Neanderthal replacement by AMH have been prominent since at least the 1980s (Leroyer and Leroi-Gourhan, 1983; Leroyer, 1988) and continue to have much traction (Finlayson, 2004; Sepulchre et al., 2007; Burke et al., 2014; Daura et al., 2017; Staubwasser et al., 2018). Global climatic records from a range of proxy sources suggest that the MUPT occurred during the climatically unstable Marine Isotope Stage 3 (MIS 3) and was preceded by a series of relatively abrupt climatic oscillations (Adams et al., 1999; Maslin et al., 2013; Rasmussen et al., 2014; Sánchez Goñi et al., 2008). The transition itself spanned a number of Dansgaard–Oeschger (DO) millennial-scale cold phases between Greenland Interstadial 12 (GI12) and Greenland Interstadial 8 (GI8) (Rasmussen et al., 2014). In addition, evidence of ice-rafted debris (IRD) from North Atlantic marine sediment cores, among other sources, attests to the significance of Heinrich Events (HE) on northern hemisphere climate conditions (Sánchez Goñi et al., 2008). In particular, HE 5 (c. 50 - 47 kya) and HE 4 (c. 39 kya) have been argued to have played an important role in the replacement of Neanderthals by AMH (Mellars, 2006; Sepulchre et al., 2007; Müller et al., 2011). It has also been argued that Neanderthals, as a mid-latitude species, only expanded their range into more northern parts of Europe during phases of relative climatic amelioration and, consequently, were detrimentally impacted by the severe cold conditions and global climatic deterioration of MIS 4 (71 - 57 kya), a situation then exacerbated by the subsequent climatic instability during MIS 3 (Finlayson, 2004). From this perspective, the Iberian Peninsula has been proposed as a potentially important 'climatic refugium', which could have provided more hospitable conditions during periods of wider climatic and environmental deterioration, perhaps facilitating the late survival of Neanderthal groups in the southern and western regions

(Zilhão and Pettitt, 2006; Finlayson et al., 2007; Jennings et al., 2011; López-García et al., 2014).

Palaeoclimate data from Greenland ice-cores and deep-sea sediments collected off the Atlantic Iberian margin and in the Western Mediterranean Sea constitute the most complete records for reconstructing environmental conditions in the Iberian Peninsula during MIS 4 and MIS 3 (Sánchez Goñi et al., 2008; Rasmussen et al., 2014). It has been suggested that during Heinrich events, mean annual precipitation (MAP) throughout the Peninsula was approximately 400 mm less than present-day values. This coincided with winter temperatures 6 - 13 °C lower. MAP values during temperate climate phases, on the other hand, were between 600 - 800 mm, with winter temperatures similar to conditions today (Cacho et al., 1999; Sánchez Goñi et al., 2008). It is argued that cold climatic phases marked by low MAP values would have likely seen the development of desert-steppe vegetation over large areas, with a dramatic reduction in vegetation cover to less than 25 % of modern values (d'Errico and Sánchez Goñi, 2003; Sepulchre et al., 2007). It is unclear, however, the extent to which reconstructions based on ice-core and deep-sea sediments, or temporally discontinuous terrestrial palynological sequences, reflect conditions across the whole of the Peninsula. Iberia is characterised by a heterogeneous mountainous topography, which when combined with Atlantic and Mediterranean climatic influences, creates local environmental conditions which can vary significantly even across relatively short distances. While additional sources of information, such palynological, palaeobotanical and palaeontological remains recovered from archaeological contexts (López-García et al., 2013; Daura et al., 2017; Ochando et al., 2019; Fernández-García et al., 2020), continue to provide valuable site-specific data, these proxies rely on physical plant and animal remains which may be subject to taphonomic or preservation biases and often do not survive or are unsuitable for the reconstruction of long-term continuous environmental sequences. This represents a considerable drawback for investigating the role of climate in Neanderthal social

and cultural evolution. It is important that archaeologists work to improve the spatio-temporal resolution of climatic reconstructions within and across the Peninsula in order to better test competing hypotheses concerning climatic deterioration during MIS 4 and abrupt climate change events, like HE 4 or HE 5, on Neanderthal populations at the local scale. This is essential if archaeologists are to disentangle the complex causal, probable and correlative relationships between coarse trends in environmental and archaeological records (see Coombes and Barber, 2005; Barnes and Dove, 2015; Contreras, 2016; Arponen et al., 2019). To this end, novel palaeoclimate proxies which focus on the microscopic and molecular record preserved in sediments represent a promising avenue of research and are the focus of the present work.

1.3. Objectives

The aim of this thesis is to present a systematic palaeoenvironmental study of two key Iberian Middle Palaeolithic sites, to yield new sources of information for approaching the relationship between Neanderthals and their environments, as well as to provide a solid base for the application of a novel microscopic and molecular approach in archaeological research. Archaeological soil micromorphology is now a well-established method in geoarchaeological studies across the world but has generally focused on aspects of site formation, post-depositional processes and human behaviour (Goldberg and Berna, 2010; Stoops et al., 2010; Nicosia and Stoops, 2017). Although climatic and environmental signatures are discernable at the microstratigraphic scale (Vliet-Lanoë, 2010), the method has rarely been combined in a systematic fashion with other sedimentary climate proxies, particularly those based on molecular and isotopic analyses of organic compounds (e.g. Bush and McInerney, 2013; Zhang et al., 2014; Jambrina-Enríquez et al., 2016; Jordan et al., 2017; Jansen and Wiesenberg, 2017). It is well known that compound-specific $^2\text{H}/^1\text{H}$ and $^{13}\text{C}/^{12}\text{C}$ ratios ($\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$) in leaf waxes are determined by climatic and environmental controls (Yang and Huang, 2003; Sachse et al., 2006; Sachse et al., 2012; Collins et al., 2013; Diefendorf and Freimuth, 2017; Wu et al.,

2018). The integration of archaeological soil micromorphology and isotopic analyses of sedimentary lipid biomarkers offers a new approach to palaeoclimate reconstruction and the potential to link climate and human behaviour at a high scale of spatial and temporal resolution. There are, however, several challenges involved. For instance, the preservation of these compounds in Pleistocene sediments is not always optimal. In addition, lipid molecular climate proxies have almost exclusively been applied in non-archaeological contexts where the potential for anthropogenic alteration of the climatic signal, for instance through burning, is entirely absent or very limited. Owing to a lack of focused research on the topic, the extent of anthropogenic alteration and the applicability of these methods in archaeological contexts is not well understood. Archaeological soil micromorphology, however, in addition to providing an alternative source of climatic and environmental information, offers one avenue for determining anthropogenic or biogenic impact on sediments and thus the integrity and suitability of sedimentary sequences for lipid molecular analyses. Consequently, in this thesis, these methods are applied together for the first time in Pleistocene archaeosedimentary contexts. The objectives are:

- i. To explore the suitability of Pleistocene archaeosediments for lipid molecular and compound-specific isotope analysis of fossil leaf waxes (*n*-alkanes) for palaeoclimate reconstruction.
- ii. To characterise the palaeoclimatic framework for the Neanderthal occupations recorded in Abric del Pastor (MIS 5/4) and El Salt (MIS 3).
- iii. To investigate the complementarity of archaeological soil micromorphology and molecular sedimentary proxies in tandem with traditional palaeoenvironmental proxies used in archaeological research, specifically charcoal, microvertebrates, macro-faunal remains, pollen and non-pollen palynomorphs.

- iv. To determine whether the environmental and climatic data from these sites implicate climate change or abrupt climate events in the disappearance of Neanderthals from Eastern Iberia.

1.4. Hypotheses

The specific hypotheses formulated and tested in this thesis are defined at the outset. In each case, a null hypothesis (H_0) will be examined through the evidence presented in this thesis and tested against a competing alternate hypothesis (H_1).

Hypothesis I:

H_0 – Archaeosediments from Middle Palaeolithic sites in Eastern Iberia *do not* preserve a microscopic and molecular record of Pleistocene climate conditions.

H_1 – Archaeosediments from Middle Palaeolithic sites in Eastern Iberia *do* preserve a microscopic and molecular record of Pleistocene climate conditions.

Hypothesis II:

H_0 – Combined microscopic and molecular analyses of sediments at the study sites *do not* allow accurate and precise reconstruction of past climatic and environmental conditions.

H_1 – Combined microscopic and molecular analyses of sediments at the study sites *do* allow accurate and precise reconstruction of past climatic and environmental conditions.

Hypothesis III:

H_0 – Sedimentary microscopic and molecular climate proxies *cannot* be usefully compared with traditional palaeoenvironmental proxies used in archaeological research.

H_1 – Sedimentary microscopic and molecular climate proxies *can* be usefully compared with traditional palaeoenvironmental proxies used in archaeological research.

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

Hypothesis IV:

H_0 – Sedimentary microscopic and molecular climate proxies *do not* indicate unstable environmental conditions during MIS 3 in Eastern Iberia.

H_1 – Sedimentary microscopic and molecular climate proxies *do* indicate unstable environmental conditions during MIS 3 in Eastern Iberia.

Hypothesis V:

H_0 – There is *no* consistent relationship between climate change or abrupt climate events and Neanderthal activity at the selected study sites.

H_1 – There *is* a consistent relationship between climate change or abrupt climate events and Neanderthal activity at the selected study sites.

1.5. Thesis structure and rationale

This work is set out in 9 chapters. Chapter 2, which follows, outlines the geoarchaeological and methods employed throughout the work. Chapters 3 to 5 outline three focused case studies which have been published or are being prepared for submission (Chapter 3 was published in *Quaternary Science Reviews* (Connolly et al., 2019)). Chapter 3 describes the application of archaeological soil micromorphology and compound-specific isotope analysis of sedimentary *n*-alkanes at the Middle Palaeolithic site of Abric del Pastor (MIS 5/4). Additional environmental proxies, which include anthracology, micro-vertebrate and macro-faunal analysis, are incorporated into this study to provide a further level of detail in selected stratigraphic units. A similar approach is described in chapter 4, where archaeological soil micromorphology and compound-specific isotope analysis of sedimentary *n*-alkanes are deployed together with a palynological study at the site of El Salt (MIS 3). Chapter 5 describes a laboratory-based experiment which investigates the impact of low-temperature combustion on $\delta^2\text{H}_{\text{wax}}$ values of different plant organs of *Celtis australis*. This study aimed to explore potential weaknesses and new applications of this novel sedimentary climate proxy in

archaeological contexts. The common element which runs through all three case studies is methodological; in each, microscopic and molecular methods are applied and show the possibilities and results of integrated research, with the overarching goal of garnering new high-resolution palaeoclimate information to establish the environmental context for the demise of Neanderthals in Eastern Iberia. Several common issues and methodological insights emerged from these case studies, and these are summarised and discussed in Chapter 6 in light of the hypotheses set out previously, followed by references in Chapter 7.

Chapter 2: Methodological background

2.1. Archaeological soil micromorphology

Archaeological deposits, or *archaeosediments*, are typically characterised by a complex interplay between geogenic, biogenic and anthropogenic factors. Information obtained at the microstratigraphic scale of observation has been shown to yield valuable insights into the nature and integrity of these deposits, by elucidating site formation processes, landscape development, environmental conditions, on-site human activities, and bioturbation or other post-depositional disturbances (Nicosia and Stoops, 2017). Soil micromorphology is the study of soils or sediments in their intact state using petrographic thin sections and polarising light microscopy. Early studies of sub-macroscopic soil properties first emerged more than a century ago (Delage and Lagatu, 1904; Agafonoff, 1929; Allen, 1930), although it was through the work of Walter Ludwig Konstantin Ritter von Kubiëna, Professor of Geology at the University of Venice, that the technique of soil micromorphology came to be formalised and more widely known (Kubiëna, 1938, 1958; Kubiëna and Ruhe, 1970). Soil micromorphology found widespread application in pedological studies through the course of the twentieth century, however, Cornwall (1958) was the first to promote its use for addressing strictly archaeological research questions. Few archaeologically oriented studies followed in the subsequent decades (Dalrymple, 1958; Romans and Robertson, 1983), however, from the mid-1980s onward the method began to be more widely applied in archaeological contexts, contributing significantly to the emerging sub-discipline of geoarchaeology, principally through the work of geologists, soil scientists and geoarchaeologists (Courty and Fedoroff, 1985; Fedoroff and Courty, 1987; Macphail, 1987; Courty et al., 1989; Macphail et al., 1990). This flurry of research activity led to the standardisation of terminology used in soil micromorphological descriptions, which facilitated the expansion of the technique and its more widespread uptake in archaeological studies. The first descriptive guidebook to find widespread use was that of Bullock et al. (1985).

This was later updated and largely replaced by Stoops (2003). An International Working Group in Archaeological Soil Micromorphology was formed in 1990, first meeting at Institute of Archaeology, University College, London, and continues to meet on an annual basis at locations throughout the United Kingdom and Europe. This has provided a platform for researchers at various stages in their careers to interact, exchange knowledge about the application of soil micromorphology in a wide variety of geological and sedimentary contexts. This has no doubt contributed to the significant increase in the number of archaeological soil micromorphological studies that have followed in the subsequent three decades since the working group was first convened (Nicosia and Stoops, 2017; Macphail and Goldberg, 2018).

Archaeological soil micromorphology can also be regarded as having contributed and benefited from concurrent developments in the field of archaeological science and the sub-discipline of microarchaeology (Weiner, 2010). Researchers now commonly complement soil micromorphological descriptions with a range of instrumental analytical techniques designed to add new levels of detail and extract additional information to aid in archaeological interpretation. Many of these techniques which focus on inorganic components can be applied directly to thin sections, such as scanning electron microscopy (SEM) (Ward et al., 2019), energy-dispersive and wave-dispersive X-ray spectroscopy (EDS/EDX/WDX) (Shillito et al. 2009), electron microprobe (EMP) (Schaefer et al., 2004), or Fourier transform infrared spectroscopy (micro-FTIR) (Haaland et al., 2017).

2.1.1. Site formation processes and palaeoenvironments at the microscopic scale

Site-formation processes refer to the combination of factors that ultimately compose the archaeological record. An accurate reconstruction of site formation processes, including the depositional environment and the nature and degree of post-depositional alterations or disturbances, is crucial for understanding the spatial integrity of archaeological materials

within site and, hence, for allowing archaeologists to develop robust interpretations (Goldberg and Macphail, 2008). Formation theory in archaeology came to the fore through the seminal work of M.B. Schiffer and the publication of his book *Formation Processes of the Archaeological Record* (Schiffer, 1987). This came on the back of Butzer's *Archaeology as Human Ecology: Method and Theory for a Contextual Approach* (Butzer, 1982), which marked a growing concern with the sedimentary contexts of archaeological sites. It also emerged in an atmosphere of much debate about how archaeologists ought to define and understand archaeological deposits (Schiffer, 1972; Binford, 1983). Schiffer roundly rejected the assumption that past human activities define the spatial patterning of excavated archaeological materials, an idea which had widespread acceptance among many of his contemporaries (Binford, 1964; McPherron, 1967; Brose, 1970). Schiffer instead argued that reliable human behavioural inference relies on a clear understanding of the archaeological context and suggested that the transformations which affect the archaeological record can broadly be grouped into two categories: those related to anthropogenic activity which he labelled *C-transforms*; and those related to geogenic or otherwise environmental processes which he labelled *N-transforms*. While much work in site formation processes throughout the 1980s and 1990s was developed in ethnoarchaeological case studies, the emphasis of formation theory on deposits, as opposed to strictly investigating artefactual assemblages, naturally aligned with the focus and emerging methodological innovations of geoarchaeological studies, in particular soil micromorphology (Goldberg, 1979; Goldberg, 1980; Fedoroff and Goldberg, 1982; Courty et al., 1989; Watez et al., 1990; Weiner et al., 1995; Simpson and Barrett, 1996). Conceptually, it came to be recognised that sedimentary deposits in archaeological contexts are in themselves artefacts of past human activities, which can be modified and transformed through processes such as trampling, sweeping, burning, or the deliberate importation of exogenous materials for flooring or bedding (Miller et al., 2013). Deposits may also be greatly altered by soil formation

(pedogenesis) or chemical diagenesis, for instance through the deposition of bird or bat guano (Karkanis and Goldberg, 2018). In the subsequent two decades, the efficacy of soil micromorphology for elucidating complex site formation processes in a wide range of environments has been well established (Karkanis et al., 2000; Mallol et al., 2009; Mallol et al., 2010; Friesem et al., 2014; Morley et al., 2017; Stahlschmidt et al., 2018; Angelucci et al., 2019; McAdams et al., 2019; Patania et al., 2019; Ward et al., 2019).

A key component for understanding depositional dynamics and site formation is the reconstruction of the local and regional environmental context and how this might have fluctuated in the time since the deposit was formed. Geoarchaeological studies have long emphasised the importance of palaeoenvironmental reconstruction (Laville, 1976; Lynch, 1986; Schuldenrein, 1986). Observation of sediments at the microstratigraphic scale can yield vital clues about local and regional environmental conditions, and palaeoenvironmental data is implicit in most soil micromorphological studies (Courty and Vallverdu, 2001; Stephens et al., 2005; Vallverdú-Poch and Courty, 2012). Soil micromorphology is well suited to the identification of diagnostic horizons and properties indicative of frost action in cold or periglacial climate conditions (Vliet-Lanoë, 2010; Krajcarz and Krajcarz, 2019; Nieuwendam et al., 2020), or past periods of aridity which can be indicated by the presence of gypsic pedofeatures, pseudomorphic voids or calcite pseudomorphs (Lebedeva-Verba and Gerasimova, 2009; Poch et al., 2018). The presence of specific microstructures, fabrics, or post-depositional features linked to wet or waterlogged environments has also been reported (Sedov et al., 2008; Mallol et al., 2009), as well as characteristic pedofeatures related to repeated cycles of wetting and drying, which induce swelling and shrinking of the matrix and deformation of pores (Pires et al., 2008; Stahlschmidt et al., 2018). Environmental and climatic information inferred from micromorphological observations provides a robust qualitative source of data to complement other proxies. One distinct advantage of the soil

micromorphological approach is the ability to establish and link contextualised environmental data to specific microfacies, allowing archaeologists to estimate the timing, duration and overall magnitude of climatic processes at the highest possible scale of resolution and construct a robust framework for investigating human-environmental interactions through time.

Several key observations arising from soil micromorphological analyses, such as the rate of sedimentation, mode of deposition, post-depositional disturbances or chemical alteration, have the potential to greatly influence the results of other sedimentary climate proxies, including lipid biomarker characterisation and CSIA. In this thesis, we present the first attempts to deploy these methods in a single integrated workflow, as a step towards providing high-resolution onsite palaeoclimate data against which archaeological records can be compared.

2.2. Lipid biomarkers and *n*-alkane biosynthesis in plants

The term *biomarker*, or biological marker, is used to describe any organic compound which can be traced to a specific biological source (Eglinton et al., 1964; Evershed, 1993). The term can be applied to a wide variety of biomolecules, although lipids have received the most attention in archaeological and palaeoecological research (Evershed et al., 1999). Peters et al. (2005) identify three key features which distinguish lipid biomarkers from most other organic compounds:

- I. Structures characterised by repeating subunits which indicate precursors were present in formerly living biological organisms.
- II. The parent biomarkers are common to specific biological organisms, normally organisms which occur frequently and are widely distributed.
- III. Upon burial, the main structural characteristics which identify the compound remain chemically stable.

Hydrocarbons are among the simpler functional classes of lipid biomarkers, and biogenic hydrocarbons are produced in a number of biotic sources (Peters et al., 2005). For instance, saturated aliphatic hydrocarbons, or *n*-alkanes, are widely distributed in nature. Cyanobacteria and algae are known to produce short-chain (low molecular weight; LMW) branched and unbranched alkanes (typically C₁₅ - C₁₉), mid-chain (medium molecular weight; MMW) alkanes are more typical of aquatic macrophytes and bryophytes (C₂₁ - C₂₅) (Cranwell et al., 1987; Ficken et al., 2000; Klavina and Kvišis, 2015), while long-chain (high molecular weight; HMW) alkanes are linked with insect cuticular lipids and more commonly plant epicuticular leaf waxes (C₂₇ to C₃₅) (Eglinton et al., 1962; Gibbs and Pomonis, 1995; Blomquist et al., 2019).

A plant cuticle can be described as a fine waxy lipophilic film which coats the epidermal surfaces of most leaves, as well as other plant organs such as non-woody stems and flowers (Post-Beittenmiller, 1996). Cuticular leaf waxes play a critical role in moderating functions which are essential for plant survival, these include the restriction of non-stomatal water loss linked to biotic and abiotic stresses, as well as protecting against adverse effects produced by exposure to ultraviolet radiation (Reicosky and Hanover, 1978; Barnes et al., 1994; Riederer and Schreiber, 2001; Cheng et al., 2019). These waxes may also play a role in protecting plants against fungal or bacterial pathogens (Jenks et al., 1994).

Plants biosynthesise the *n*-alkane component of cuticular leaf waxes from precursor saturated very long-chain fatty acids (VLCFA). Most cuticular leaf wax components are derived from VLCFA chains that are 20 to 32 carbons in length (Post-Beittenmiller, 1996). The reactions involved in leaf wax biosynthesis are localised in the epidermal cells (Kolattukudy, 1968; Kunst and Samuels, 2003; Tinto et al., 2017). Initially, de novo fatty acids C_{16:0} and C_{18:0} are synthesised in plastids, membrane-bound organelles located in the cells of plants, through a series of consecutive enzymatic steps produced by soluble enzymes which form the fatty acid

15

synthase complex (FAS) (Ohlrogge et al., 1993; Jaworski et al., 1994). Four basic reactions take place, condensation, reduction, dehydration, and another reduction, which produce a two-carbon elongation of the acyl chain (Post-Beittenmiller, 1996). A series of elongation steps linked to microsomal enzymes subsequently follow which extend the C_{16:0} and C_{18:0} fatty acids producing VLCFA chains in a process which is catalysed by membrane-associated multienzyme complexes referred to as fatty acid elongases (FAE). These reactions are analogous to those involved in the synthesis of de novo fatty acids (von Wettstein-Knowles, 1982). These VLCFA chains are required to synthesise the cuticular wax lipids, and multiple rounds of elongation are necessary to produce the requisite acyl chain lengths. Chain length specificity is governed by interactions between different elongases, though the precise metabolic roles played by specific elongase condensing enzymes is not well understood (Kunst and Samuels, 2003; Tinto et al., 2017). In the vast majority of plant species, wax biosynthesis occurs through two major pathways: an acyl reduction pathway which produces primary alcohols and wax esters, and a decarbonylation pathway which produces aldehydes, alkanes, secondary alcohols and ketones. In many plants, the fatty acid elongation reactions are shared between both the acyl reduction pathway and the decarbonylation pathway, which thus differ only in terms of the enzymes acting on the VLCFA chains and their derivatives (Post-Beittenmiller, 1996).

For the production of *n*-alkanes through the decarbonylation pathway, aldehydes are first produced by a membrane-bound fatty acyl-CoA reductase acting on VLCFA precursors. These aldehydes are subsequently decarbonylated to odd-chain alkanes (C_nH_{2n+2}), with one less carbon atom compared to its fatty acid precursor, in a reaction which is catalysed by an aldehyde decarbonylase (Post-Beittenmiller, 1996; Kunst and Samuels, 2003; Tinto et al., 2017).

2.2.1. Sedimentary *n*-alkanes in palaeoenvironmental research

Sedimentary *n*-alkanes derived from leaf waxes have emerged in recent years as a robust proxy in palaeoclimatological and palaeoecological research (e.g. Bush and McInerney, 2013; Zhang et al., 2014; Jambrina-Enríquez et al., 2016; Jordan et al., 2017; Jansen and Wiesenberg, 2017). These compounds have particularly high research value in these fields due to their hydrophobic properties and strong resistance to post-depositional degradation. In suitable depositional contexts, *n*-alkanes can preserve over geological timescales (Eglinton et al., 1964; Eglinton and Hamilton, 1967; Cranwell, 1981). Researchers employ a suite of *n*-alkane-specific molecular ratios as proxies for inferring palaeoenvironmental information, including biogenic source (e.g. terrestrial versus aquatic plants), alteration (e.g. microbial reworking) or overprint of organic matter (e.g. through root contribution) (Jansen and Wiesenberg, 2017). The most common molecular ratios for palaeoenvironmental reconstruction are the Carbon Preference Index (CPI) (Bray and Evans, 1961) and the Average Chain Length (ACL) (Poynter et al., 1989; Freeman and Pancost, 2013).

Compound-specific isotope analysis (CSIA), which differs from the bulk isotope analysis more commonly employed in archaeological research by targeting individual compounds, allows researchers to trace the carbon and hydrogen sources of specific lipid biomarkers, adding new layers of information about palaeoclimate and palaeovegetation (Hayes et al., 1990; Burgoyne and Hayes, 1998; Hilkert et al., 1999). The carbon isotopic ratio ($^{13}\text{C}/^{12}\text{C}$; $\delta^{13}\text{C}_{\text{wax}}$) of cuticular leaf waxes have been shown to be a sensitive record of perturbations in the carbon cycle, local vegetation dynamics, and climate (Diefendorf et al., 2011; Magill et al., 2013; Diefendorf and Freimuth, 2017), while the stable isotopic ratio of deuterium and hydrogen (D/H; $\delta^2\text{H}_{\text{wax}}$) can record fluctuations in precipitation and the hydrological cycle (Sachse et al., 2006; Sachse et al., 2012). An increasing number of studies in recent years have demonstrated that when appropriate consideration is afforded to the various biological and climatological variables

17

which influence isotopic fractionation in wax lipids, these proxies can be effectively deployed for high-resolution palaeoclimate and palaeoenvironmental reconstructions (Yang and Huang, 2003; Bi et al., 2005; Sachse et al., 2006; Liu and Yang, 2008; Collins et al., 2013; Ladd and Sachs, 2013; Garcin et al., 2014; Gamarra et al., 2016; Wu et al., 2018). Variables may include factors such as vegetation type, evapotranspiration, salinity, aridity, seasonality or temperature (Sachse et al., 2012; Diefendorf and Freimuth, 2017; Liu and An, 2018; Magill et al., 2019). To date, however, few studies have provided robust contextual descriptions of the sedimentary environments sampled for leaf waxes, omitting significant information about depositional and post-depositional processes and potentially hampering interpretations of the molecular data. Bioturbation processes related to soil micro and meso-fauna, often not visible at the macroscopic scale of observation, may significantly disrupt the stratigraphic integrity of the sedimentary sequence. In addition, common anthropogenic activities, such as burning, can potentially alter *n*-alkane molecular ratios and isotopic values. Before these proxies can be reliably applied in archaeological settings, it is critical that the integrity and suitability of the depositional environment are established. We suggest that archaeological soil micromorphology, a well-established method for approaching site formation processes and sedimentary dynamics at the highest possible spatial and temporal resolution, is uniquely well-suited for this task. Observations at the microstratigraphic scale also offer an additional source of environmental and climatic information to complement the molecular data (Courty, 2001; Courty and Vallverdu, 2001; Mallol et al., 2009; Mallol et al., 2010; Stoops et al., 2010; Nicosia and Stoops, 2017).

Abstract

This paper presents a multiproxy palaeoenvironmental study from Abric del Pastor (Alcoy, Spain), a rock shelter which has yielded evidence for Middle Palaeolithic human occupation. The sedimentary sequence has been analysed for lipid biomarker *n*-alkane abundances (ACL, CPI), compound-specific leaf wax $\delta^2\text{H}$ and $\delta^{13}\text{C}$, and bulk organic geochemistry (TOC, %N, %S), providing a record of past climate and local vegetation dynamics. Site formation processes have been reconstructed through the application of soil micromorphology. Analyses

of anthracological, microvertebrate and macrofaunal assemblages from selected subunits are also presented here. Our data indicates that a variable climate marked by predominantly cold conditions persisted through most of the sequence and that Neanderthal occupations in stratigraphic unit IVd, assigned to MIS 4 or late MIS 5, occurred in a landscape setting characterised by a mosaic of biotopes. The presence of key resources inside the ravine where the site is located suggests that the occupation of the rock shelter may have been strategically motivated by a subsistence and mobility strategy which focused on zones of localised ecological resilience, such as intra-mountainous valleys or ravines, during periods of global or regional environmental downturn.

3.1. Introduction

Abric del Pastor, Alcoy, Spain (Fig. 3.1) hosts a sequence containing Upper Pleistocene deposits overlain by reworked Holocene sediments. The site has yielded evidence for multiple short-term Neanderthal occupation events (Machado et al., 2013). Archaeological remains recovered from the site include lithic artefacts (Galván Santos et al., 2007; Hernández et al., 2010; Machado et al., 2013), charcoal (Vidal-Matutano et al., 2015, 2017) and faunal remains (Sanchis et al., 2015; Pérez et al., 2017). In addition, at least 17 combustion features have been identified throughout the sequence. Ongoing excavations have produced a sedimentary sequence which has been divided into six primary lithostratigraphic units (S.U. I - VI), with further subdivisions therein. The current chronological framework is based on ESR dates obtained from animal teeth recovered in S.U. IVb ($48 \text{ kya} \pm 5000 \text{ } 1\sigma$) and S.U. VI ($62 \text{ kya} \pm 12,000 \text{ } 1\sigma$), as well as an OSL date from a quartz grain recovered in S.U. IVd ($63 \text{ kya} \pm 5000 \text{ } 1\sigma$) (Mallol et al., 2019) (Fig. 3.2) (further information on the methods used for dating is provided in Appendix 1 Table 1 and 2). Taking into consideration the error ranges, these dates frame the sequence at Abric del Pastor between 43 kya and 72 kya, covering the whole of MIS 4 and potentially extending into late MIS 5 and/or early MIS 3. Although the current dates are

stratigraphically coherent, additional samples are required to corroborate the site chronology. With this in mind, our aim here is to provide independent climatic and environmental data, recovered from deposits containing direct evidence for human occupations, against which future hypotheses concerning the chronology of the site and Neanderthal responses to climate change can be further tested.

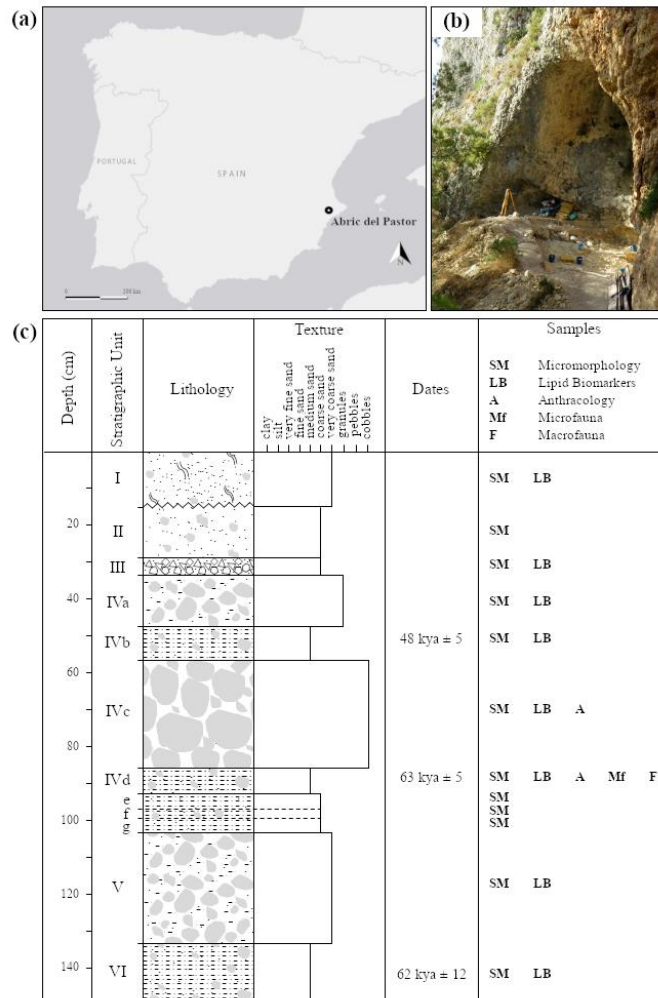

Figure 3.1 Location of site (a), drone image of the rock shelter (b) and stratigraphic log showing the sampling locations for the different proxies used in the current study (c). Dates are reported at the one sigma (1σ) confidence level.

The Iberian Peninsula is widely regarded as crucial for understanding how Neanderthals responded to fluctuations in environmental conditions (Jiménez-Espejo et al., 2007; Wood et al., 2013; Marín-Arroyo et al., 2018), and the prospect of an MIS 4 setting for the occupations recorded in S.U. IVd warrants consideration, as the palaeoenvironmental record for this marine isotope stage in the Iberian Peninsula remains poorly resolved in comparison to MIS 5 (e.g. Blain et al., 2014; Torres et al., 2015; Daura et al., 2015; Ochando et al., 2019) or MIS 3 (e.g. d'Errico and Sánchez Goñi, 2003; Blain et al., 2013; López-García et al., 2014; Sánchez-Hernández et al., 2014; Alcaraz-Castaño et al., 2017; Daura et al., 2017). There is a paucity of long-term continuous terrestrial sequences and site-specific records for the peninsula, although off-shore marine records suggest that rapid global climatic cooling and a significant decrease in sea-surface temperatures (SST) may have driven the development of semi-desert vegetation (Sánchez Goñi et al., 1999; Sánchez Goñi and d'Errico, 2005). The peninsula, owing to its latitudinal range, its diverse topography and the climatic influence of the Atlantic Ocean and Mediterranean Sea, is characterised by considerable climatic diversity in which local environmental conditions change abruptly over relatively short distances (Rivas-Martínez, 1987; López-García et al., 2013). In this context, localised zones of ecological resilience (Holling, 1973; Gunderson, 2000), or vegetation refugia, may have provided conditions favourable to human occupation and subsistence during periods of global climatic deterioration.

Figure 3.2 Comparing the site chronology from Abric del Pastor (S.U. IVc, IVd and S.U. VI, error bars report the one sigma (1σ) confidence level) with $\delta^{18}O$ record of the NGRIP ice core (North Greenland Ice Core Project members, 2004). ESR (IVb and VI) and OSL (IVd).

New evidence and site-specific environmental records are required to improve our understanding of the role which climate may have played in Neanderthal social and cultural evolution. From this perspective, we investigate carbon and hydrogen isotope values of individual lipid biomarkers (*n*-alkanes) to gain insight into hydroclimatic and vegetation dynamics through the stratigraphic sequence at Abric del Pastor (S.U. I – VI; 110cm). These proxies are now widely used for palaeohydrological and palaeoecological reconstructions (Bi et al., 2005; Sachse et al., 2012; Collins et al., 2013, 2017; Diefendorf and Freimuth, 2017; Jordan et al., 2017; Norström et al., 2018; Wu et al., 2018). Sedimentary *n*-alkanes are saturated aliphatic hydrocarbons derived from the epicuticular leaf waxes of vascular plants. Plants usually produce *n*-alkanes with a range of different chain lengths and an odd-over-even predominance (Eglinton et al., 1962; Eglinton and Hamilton, 1967). These compounds have been shown to preserve well in sediments and yield valuable information about their biological source, making them well suited for palaeo-ecosystem reconstructions. Compound-specific $\delta^{13}C$ and δ^2H of individual *n*-alkanes, which record both ecologic (carbon isotope) and hydrologic (hydrogen isotope) information, are also increasingly being utilised in terrestrial

palaeoenvironmental research (Yang and Huang, 2003; Collins et al., 2013, 2017; Jambrina-Enríquez et al., 2016; Uno et al., 2016; Wang et al., 2016; Wu et al., 2018). Different processes govern the carbon and hydrogen isotopic compositions of leaf waxes, thus revealing different information about past environmental conditions.

Among other factors, $\delta^{13}\text{C}_{\text{wax}}$ values are influenced by the ratio between ^{12}C and ^{13}C in the atmosphere ($\delta^{13}\text{C}_{\text{atm}}$) and isotopic discrimination during photosynthetic carbon fixation ($\Delta\delta^{13}\text{C}$). Studies have demonstrated that differences in ^{13}C fractionation among C3 and C4 plants are recorded by leaf wax $\delta^{13}\text{C}$ values, making it possible to discriminate between these vegetation types. Other factors such as water availability, taxa, light intensity, nutrient status and canopy effects also influence $\delta^{13}\text{C}_{\text{wax}}$ values, to various extents (Diefendorf et al., 2010; Kohn 2010; Diefendorf and Freimuth, 2017). $\delta^2\text{H}_{\text{wax}}$ values are determined by the relative abundance of hydrogen (H) and deuterium (D) in the source water used by plants during leaf wax synthesis (Sachse et al., 2012). As leaf water ultimately derives from precipitation, compound-specific isotope analysis of sedimentary *n*-alkanes can yield useful information about the hydrogen isotopic composition of past precipitation ($\delta^2\text{H}_p$). $\delta^2\text{H}$ values of mean annual precipitation (MAP) have been shown in certain cases to correlate positively with $\delta^2\text{H}_{\text{wax}}$ values (Sachse et al., 2012). The hydrogen isotopic composition of leaf waxes is also, however, influenced by other factors. Liu and An (2018) identify precipitation $\delta^2\text{H}$, plant type and evapotranspiration as primary controls over $\delta^2\text{H}_{\text{wax}}$, while additional factors such as aridity, seasonality, temperature and relative humidity can act as second level or third level controls.

Here, we aim to frame our biomolecular data within a broad reconstruction of site formation processes, which are investigated through the application of soil micromorphology. This approach also offers the opportunity to identify features or processes at the microstratigraphic scale which may be indicative of certain environmental conditions (Courty 2001; Courty and

Vallverdu, 2001; Nicosia and Stoops 2017). We also include analyses of anthracological, microvertebrate and macrofaunal assemblages from subunit S.U. IVd. We focus our analyses on S.U. IVd as OSL dating implies a possible MIS 4 setting for the Neanderthal occupations recorded in this subunit.

3.2. Regional setting and site background

3.2.1. Abric del Pastor

Abric del Pastor is a rock shelter situated 820 m a.s.l on a north facing slope of the Barranc del Cinc ravine in the Mariola mountain range, Alcoy, south-eastern Spain. The site is located approximately 30 km from the modern coastline, encompassing an area of c. 60 m² and occurs in a geological context characterised by Miocene Tortonian formations composed of bioclastic calcirudites. The shelter is adjacent to the Serpis river and was formed through phreatic erosional processes acting on a karstic paleotube. Processes of chemical dissolution and mechanical weathering, for instance through repeated freeze-thaw cycles during climatic cooling episodes, appear to be the primary agents driving the sedimentation at the site through the disintegration of autochthonous limestone.

Mario Brotons led the first excavations at Abric del Pastor in 1953. This work focused on the central area of the modern excavation surface. A considerable number of faunal remains and lithic artefacts were recovered (for instance >2400 lithics), however, poor record keeping has rendered these materials devoid of any reliable contextual information. Brotons' excavations affected only a small area and the uppermost layers of the archaeological deposits (S.U. I, II, III), leaving most of the site intact (Galvan et al., 2007; Molina et al., 2010). Current excavations, directed by the Universidad de La Laguna, Tenerife, are ongoing since 2005.

3.2.2. *Sedimentary sequence*

S.U. I (13 - 65 cm thickness) is formed by episodic Holocene sedimentation. This unit is composed of heavily bioturbated and reworked humic topsoil yielding Middle Palaeolithic industries alongside diagnostic Neolithic pottery fragments and other modern anthropogenic debris.

S.U. II (08 - 13 cm thickness) is an isolated pocket of matrix-supported dark brown sandy gravelly sediment truncated by *S.U. I* at the NW corner of the excavation area. Components include faunal remains and a single combustion feature.

S.U. III (03 - 12 cm thickness) is a thin, locally discontinuous, partially cemented carbonate crust composed of calcareous sand and fine to medium gravel. This unit has yielded few archaeological remains.

S.U. IV (55 - 72 cm thickness) is composed of laterally discontinuous, clast-supported, limestone cobble beds (subunits IVa, IVe and IVg) interspersed by loosely compacted, matrix-supported, fine-grained, calcareous sandy-gravelly deposits with frequent limestone cobbles (subunits IVb, IVd and IVf). Subunit IVc, which extends across the whole excavation surface, comprises boulders and large angular cobbles with very little fine material, resulting from one or more significant roof collapse events. *S.U. IV* has yielded abundant archaeological material including lithics, faunal remains, combustion features and charcoal. Previous archaeostratigraphic analyses of the lithic record incorporating Raw Material Units (RMU's) and refits has identified between 4 and 6 short-term Neanderthal occupation episodes within subunits IVa, IVb and IVc alone (Machado et al., 2013).

S.U. V (15 - 25 cm thickness) is notable for a concentration of large boulders in the SW part of the excavation surface, representing a partial collapse of the shelter roof. The bulk of the

26

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

deposit is composed of loosely compacted, matrix-supported, fine-grained calcareous sand with fine to medium gravel.

S.U. VI (indeterminate thickness) is composed of moderately compacted sandy-silty sediment with a relatively low proportion of small and medium gravel. Despite excavation of this unit having so far been limited to the 4 m² sondage situated at the back of the rock shelter (Appendix 1 Figure 1), a dense concentration of combustion residues, lithics and faunal remains have been recorded.

3.3. Material and methods

Bulk sediment samples representing S.U.'s I, III, IV, V and VI were collected in vertical sequence from the north profile (A7[1], Z7[2], see Appendix 1 Figure 1). S.U. II has not been analysed for lipid biomarkers or lipid biomarkers because this is a discreet unit only present in a small pocket at the NW corner of the excavation surface. All samples were collected using stainless steel spatulas washed with MeOH and dichloromethane (DCM), using Al foil to avoid phthalate contamination from plastic bags. Samples were then stored at -20 °C and subsequently sub-sampled for lipid biomarker analyses and organic geochemistry.

3.3.1. Total Organic Carbon (TOC), % Sulphur (%S), % Nitrogen (%N)

TOC (%) and %S was analysed with a LECO SC 144DR furnace. Measurement accuracy is 1% RSD *or* ± 25 ppm for carbon (RMS 0.053648) and 1% RSD *or* ± 2.5 ppm for sulphur (RMS 0.044829). %N was measured using a VARIO MAX CN elemental analyser. The standard deviation is <0.3% and the rate of recovery >99.5%. Analyses were carried out at the Instituto Pirenaico de Ecología (IPE-CSIC), Spain.

3.3.2. Extraction and analysis of *n*-alkanes

Extraction and analyses of lipids as well as subsequent isotopic analyses of all samples were carried out at the Archaeological Micromorphology and Biomarkers Laboratory (AMBI), Universidad de La Laguna, Tenerife. 20g sediment samples were dried at 60 °C for 48 hours and subsequently ground and homogenised using an agate pestle and mortar cleaned with MeOH and dichloromethane (DCM). All non-volumetric glassware used for lipid extraction were thoroughly cleaned, solvent washed with MeOH and calcined at 450 °C for 10 hours prior to extraction to eliminate potential contaminants. Lipids from 20g sediment samples were extracted in 150mL dichloromethane/methanol (DCM:MeOH 9:1) by ultrasonic extraction (three cycles of 30 minutes) and centrifugation (three cycles at 4700rpm). The total lipid extract (TLE) was then concentrated under a steady flow of N₂ gas at 40 °C in a rotary evaporator. The TLE was subsequently reconstituted using DCM and separated into fractions of differing polarity by solid phase extraction (SPE) through a silica gel column (1g silica, 70-230 mesh and 0.1g sand 50-70 mesh, both previously calcined at 450 °C for 10 hours).

Here we present results of fraction 1 (F1: *n*-alkanes), which was eluted with $\frac{3}{8}$ of dead volume (DV) in *n*-hexane. F1 was subsequently concentrated under a steady stream of N₂ gas at 40 °C in an Organomation rotary evaporator and stored at -20 °C. Prior to measurement, 3µL of internal standard (IS) 5α-androstane 8mg/L was added and the volume was completed with 150 µL of DCM. F1 was analysed by gas chromatography with a coupled mass-selective detector (GC-Agilent 7890B, MSD Agilent 5977A) equipped with a HP-5MS capillary column (30m, ID: 250 µm, film thickness 0.25 µm). A temperature program was applied with an initial temperature of 70 °C for 2 min and a heating rate of 12 °C/min to 140 °C, and a final temperature of 320 °C with a heating rate of 3 °C/min for 3 min, using a Helium carrier gas

28

Firmado por: Rory Connolly . UNIVERSIDAD DE LA LAGUNA	Fecha: 17/02/2021 14:01:27
Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

(2mL/min). The PVT injector was held at a split ratio of 5:1 at an initial temperature of 70 °C for 0.85 min and heated to 300 °C at a programmed rate of 720 °C/min.

Compounds were identified by comparison of their retention times and mass spectra to those of reference compounds (mix C₈-C₄₀ and 5 α -androstane, Supelco) and mass spectral library databases (NIST). Analytes were quantified using calibration curves obtained by plotting the ratio Area/Area_{IS} versus the concentration of each reference compound, with correlation coefficients higher than 0.995. The *n*-alkane concentration is expressed as μg of individual compound per gram of dry sample ($\mu\text{g gds}^{-1}$). Error ranges for individual *n*-alkanes are reported as standard deviation (Appendix 1 Table 3).

To evaluate the distribution of *n*-alkanes we used the average carbon length (ACL) and Carbon Preference Index (CPI). Indices such as ACL and CPI yield important information on the potential sources of sedimentary OM. ACL values, which are broadly structured by phylogenetic relationships, reflect changes in vegetation structure through a sedimentary sequence. Temperature and hydrological controls, however, also play a role in determining ACL values within individual plant communities (Sachse et al., 2006; Diefendorf et al., 2015a). CPI values are related to the odd-over-even predominance (OEP) of *n*-alkanes, where values >5 have typically been associated with epicuticular wax of higher plants and lower values ~1 with bacteria or algae (Cranwell et al., 1987). CPI has also been employed as an indicator of *n*-alkane degradation in sediments, where low temperatures and dry conditions correspond to low diagenetic rates resulting in increased CPI values, and increased temperatures with more humid conditions correspond to higher diagenetic rates and lower CPI values (Kuder and Kruge, 1998; Xie et al., 2004; Ortiz et al., 2010). CPI values vary considerably within and amongst different plant species, however, so a cautious approach should be taken to the use of CPI as a quantitative indicator of *n*-alkane degradation (Bush and McInerney, 2013). CPI

29

Firmado por: Rory Connolly . UNIVERSIDAD DE LA LAGUNA	Fecha: 17/02/2021 14:01:27
Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

values can also be affected by thermal degradation through the incorporation of charred biomass (Eckmeier and Wiesenberg, 2009; Wiesenberg et al., 2009; Diefendorf et al., 2015b; Wang et al., 2017). As such, these values are best interpreted in conjunction with other proxies.

The ACL metric, originally defined by Poynter et al. (1989), was calculated here following the recommendations of Freeman and Pancost (2014) using the C₁₈ - C₃₅ interval:

$$ACL_{18-35} = \frac{\sum(C_i \times [C_i])}{\sum[C_i]}; 18 \leq i \leq 35$$

The CPI value (C₁₈ to C₃₅) was calculated following the equation set out in Bray and Evans (1961):

$$CPI_{18-35} = \left[\frac{\sum C_{19-35 \text{ odd}}}{\sum C_{18-34 \text{ even}}} + \frac{\sum C_{19-35 \text{ odd}}}{\sum C_{20-36 \text{ even}}} \right] \times 0.5$$

3.3.3. Gas Chromatography – isotope ratio MS (GC-IRMS)

Carbon and hydrogen isotope analysis of individual *n*-alkanes was carried out using a Thermo Scientific Isotope Ratio Mass Spectrometer Delta V Advantage coupled to a GC Trace1310 through a ConFlo IV interface with a temperature converter GC Isolink II. The GC was fitted with a Trace Gold 5-MS (Thermo Scientific) fused silica capillary column ((5%-diphenyl)-dimethylpolysiloxane, 30 m length x 0.25 mm i.d., 0.25 µm film thickness). Helium was used as the carrier gas at a flow rate set at 1.5 mL/min. All measurements were repeated three times. Data acquisition and processing were carried out using the Isodat 3.0 software (Thermo Scientific).

Carbon and hydrogen isotope values are reported for *n*-alkanes C₂₉ and C₃₁ because these compounds were consistently present in sufficient concentrations for isotopic analyses. Samples were injected by means of a Programmed Temperature Vaporising injector (PTV) in splitless mode, with the temperature increasing from 60 °C to 79 °C (held 30 s, rate 10 °C/min), then to 325 °C (held 3 min) at a rate 10 °C/s and finally to 350 °C (held 3 min) at 14 °C/s. The

Firmado por: Rory Connolly . UNIVERSIDAD DE LA LAGUNA	Fecha: 17/02/2021 14:01:27
Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

temperature programme comprised a 2 min isothermal period at 70 °C increasing to 140 °C (held 2 min) at a rate of 12 °C/min, followed by an increase period to 320 °C (held 15 min) at 3 °C/min. Combustion reactor temperature was maintained at 1000 °C for carbon isotope analysis. The high temperature conversion (HTC) oven was maintained at 1420 °C for hydrogen isotope analysis. Obtained values were normalised to the Vienna Pee Dee Belemnite (VPDB) scale ($\delta^{13}\text{C}$) and Vienna Standard Mean Ocean Water (VSMOW) scale ($\delta^2\text{H}$) using a *n*-alkane Schimmelmann type A6 mixture (*n*-C₁₆ to *n*-C₃₀) of known isotopic composition from Arndt Schimmelmann (Biogeochemical Laboratories, Indiana University). Certificate of analysis indicates that data for *n*-alkane Schimmelmann type A6 mixture have a precision of $\pm 0.05\%$ for $\delta^{13}\text{C}$ and $\pm 1.5\%$ for $\delta^2\text{H}$. Reproducibility was better than $\pm 0.5\%$ for carbon isotope measurements and better than $\pm 5.0\%$ for hydrogen isotope measurements.

To investigate the processes governing the hydrogen composition of sedimentary *n*-alkanes, a robust dataset of the isotopic signatures of potential sources, such as precipitation, is required. Here we consider monthly precipitation amount and precipitation $\delta^2\text{H}$ ($\delta^2\text{H}_p$) data available from two GNIP stations near the study area for comparison (Global Network for Isotopes in Precipitation; IAEA/WMO, 2006).

3.3.4. Micromorphology

Intact, oriented blocks of sediment from all stratigraphic units were extracted from selected profiles and from across the excavation surface for micromorphological analyses. The goal of applying this technique was to characterise site formation processes and identify features or processes at the microstratigraphic scale, which could indicate particular climatic or environmental conditions.

Samples were oven dried at 60 °C for 48 hours and subsequently impregnated with a mixture of polyester resin (Palatal strained resin UN1866, TNK composites), styrene (Styrene monomer [CAS: 100-42-5] UN2055, TNK composites) and catalyser (Luperox [CAS: 78-93-3], TNK composites) in a 7:3:0.1 ratio. The hardened blocks were then cut in 1 cm-thick slabs using a Euro-Shatal M31100 radial saw. Samples collected during archaeological field seasons 2010 - 2015 were sent to Spectrum Petrographics (Vancouver, WA, USA) for thin section manufacture (7 cm x 5 cm x 30 µm). Samples collected during the 2016 - 2018 field seasons were processed at the Archaeological Micromorphology and Biomarker Laboratory (AMBI), Universidad de La Laguna, Tenerife. Micromorphological analyses were carried out using a Nikon E200 polarising microscope following the standard guidelines set out in Stoops (2003) and Nicosia and Stoops (2017).

3.3.5. Anthracology

During the archaeological field seasons carried out between 2013 and 2016 the sediment excavated from across the entire excavation surface of S.U. IVc and S.U. IVd was processed by systematic flotation using 1.0 and 0.2 mm sieves. S.U. IVd is subdivided into IVd1, IVd2, IVd3, IVd4 and IVd5, representing distinct, locally discontinuous textural facies assigned during excavation of this unit. In this paper, scattered charcoal from these units are included, excluding the concentrated charcoal from the combustion features. Scattered charcoal spread over human living surfaces, having accumulated from an undefined number of combustion and occupation events, are widely accepted as reflecting conditions within the local environment (Badal and Heinz, 1991; Badal 1992; Chabal, 1997).

For the taxonomic identification of specimens, each fragment of charcoal was fractured manually to provide transversal, tangential and radial sections using a Nikon Optiphot-100 bright/dark field incident light microscope with 50-500x magnification. Botanical

identification was performed with specialised plant anatomy atlases (Jacquiot et al., 1973; Schweingruber, 1976, 1990) and the reference collection of modern charred woody taxa from the Department of Prehistory, Archaeology and Ancient History, University of Valencia. Spatial information relating to the current distribution of taxa has been obtained from the database of the Anthos Project (www.anthos.es) and processed using GIS software (Quantum GIS v.2.10.1 “Pisa”).

3.3.6. *Microvertebrate study (S.U. IVd)*

Microvertebrate remains

The small vertebrate fossil remains studied in this work consist of isolated dental and bone fragments collected during the 2013 archaeological field season from S.U. IVd, from across the excavation surface. The fossils were processed, sorted and classified using a Leica MS5 binocular microscope. Photographs were taken with a scanning electron microscope at Central Support Facility for Experimental Research (SCSIE) of the Universitat de València. Vertebrate fossils were identified following the anatomical nomenclature and measurement methods provided by van der Meulen (1973), Rabeder (1981) and Jeannet (2000) for arvicolines, van der Weerd (1976) for murids, Daams (1981) for glirids, Reumer (1984) for soricids, Bailon (1999) for amphibians, Roček (1984), Bailon (1991), Barahona (1996) and Barahona and Barbadillo (1997) for lacertids and Szyndlar (1984) and Blain (2009) for snakes. The taxonomic classification follows Wilson and Reeder (2005) for mammals, Uetz and Hošek (2015) for reptiles and Frost (2015) for amphibians.

Palaeoecological reconstruction (microvertebrates)

To reconstruct the climatic conditions of S.U. IVd, the Mutual Ecogeographic Range (MER) method has been applied to the assemblage (Blain et al., 2009; Blain et al., 2016). This consists of identifying regions where the recorded species are currently found and extrapolating the

Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

current mean values of these regions' climatic parameters as representative climate estimations for the studied site. This procedure suggests avoiding those species whose distribution is strongly affected by perturbing parameters, such as human pressure. Hence, *Microtus cabreræ*, taxon registered in S.U. IVd, has not been included in this study because it has suffered a range contraction in modern times and many subpopulations are small, fragmented and subject to major inter-annual fluctuations (Laplana and Sevilla, 2013; Pita et al., 2014). Biogeographic cartography of small mammal species in Spain, recorded as presence/absence of each taxa in a 10 x 10 km UTM square grid, was obtained from Palomo et al. (2007), while amphibians and reptiles came from SIARE (AHE, 2016). Climatic information (MAT, mean annual temperature; MAP, mean annual precipitation; MTW, maximum temperature of warmest month; MTC, minimum temperature of coldest month; PWM, precipitation of wettest month; PDM, precipitation of driest month) for these locations was obtained from the World Clim 1.4 database with a 30 arcseconds resolution grid (Hijmans et al., 2005). The resulting climatic parameters were compared with the current climate data from the nearest weather station to the site (Alcoy). Further details of the microvertebrate study methods and taphonomic remarks on the assemblage are given in Appendix 1.

3.3.7. Macrofaunal study (S.U. IVd)

Zooarchaeological methods

Zooarchaeological and taphonomic analyses of faunal material recovered during the excavation of S.U. IVd were performed using established standard methods (Lyman, 1994; Reitz and Wing, 2008). Where present, material was recorded for all excavation squares across the excavation surface. Remains were taxonomically and anatomically identified, except in specimens with insufficient information. Those remains were classified into three categories (long, flat or articular) and associated with a weight-size category based on bone density,

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

circumference, and cortical surface thickness. Weight-size categories were determined in keeping with archaeological examples (Uerpmann, 1973; Bunn, 1986) and current weight references based on wild male specimens (Palomo et al., 2007): large-sized (> 300 kg), medium-sized (100-300 kg), small-sized (5-100 kg) and very small-sized (< 5 kg). Five abundance measures were employed: number of remains (NR), number of identified specimens (NISP), the minimal number of elements (MNE), the minimal number of individuals (MNI) and the minimal animal units (MAU). To assess the assemblage's integrity, we calculated the fragmentation rate, the relative abundance (%RA) and the standardised MAU (%MAU). The last of these was used to calculate the differential preservation index by weight-size, applying the Pearson's r and Kendall's tau correlation coefficient test with Past 3.12© free software. Published data was referred to for large and medium-sized animals (Kreutzer, 1992; Lam et al., 1999) and for small-sized animals (Lyman, 1984; 1985; 1994). Further information on the methods used for the study of the macrofaunal material is provided in Appendix 1.

Palaeoecological reconstruction (macrofauna)

The formalisation of indicator species according to a bioclimatic classification has been applied here (Hernández-Fernández, 2001; Rodríguez, 2013; Walter, 1973). A table has been constructed with the theoretical distribution of species according to different biomes or Climate Restriction Index (CRI). The distribution in the reference material is established for mammalian species, in our work we have also included the theoretical distribution of other taxa registered in the set, i.e. birds and tortoises. Once the CRI is calculated, the bioclimatic component (BC) of the set for each biome is obtained by means of the formula $BC = (\sum CRI_i) * 100 / S$, where S is the number of species and CRI_i the index of climatic restriction of each of the species. Previously calculated discriminant functions are applied from a wide database of localities and species (Hernández-Fernández, 2001, 2006; Hernández-Fernández and Peláez-Campomanes, 2003, 2005), in order to obtain data such as annual average temperature

(AAT) or precipitation (AAP). From this, it is possible to infer the most probable biome for our faunal assemblage (Pérez et al., 2017).

3.4. Results

3.4.1. Total Organic Carbon (TOC), % Sulphur (%S), % Nitrogen (%N)

TOC ranged from 0.06 to 3.91% with an average of 1.11% (Fig. 3.3). The highest concentration was recorded in the uppermost part of S.U. I, while the lowest concentration of TOC was recorded in S.U. V. Mild fluctuations and a generally decreasing trend is observed down-profile, with the exception of S.U VI, where there is a slight increase of 0.8%. TS values ranged between 0.01% and 0.07%, with an average value of 0.03% (Fig. 3.3). The maximum concentration of TS, 0.07%, is recorded in the uppermost part of S.U I. The lowest values for TS are recorded in S.U. IVc and IVd. TN values ranged from 0.01% to 0.29%, with an average TN value through the sequence of 0.07% (Fig. 3.3). The maximum value of 0.29% is recorded as a sharp increase in the lower part of S.U. I. Mild fluctuations are observed down-profile between 0.01% and 0.03%.

Figure 3.3 Total organic carbon (TOC,%), total nitrogen (TN,%), and total sulphur (TS,%).

3.4.2. Sedimentary leaf waxes

Total *n*-alkane concentration ranged between 0.04 and 1.59 $\mu\text{g/g}$ dry sediment. Most samples through the sequence yielded *n*-alkane distributions with a predominance of long-chain compounds ($\text{C}_{29}\text{-C}_{35}$), consistent with higher order vascular terrestrial plants (Fig. 3.4) (Table 3.1), although samples collected from S.U. IVc and S.U. IVd also show input from mid-chain length compounds ($\text{C}_{23}\text{-C}_{27}$). Even-numbered homologues recorded in S.U. IVb (lower) and S.U. VI were below the limit of quantification, so CPI values for those units are not included here. CPI values through the sequence are generally low, with a minimum of 0.7 (S.U. V) and a maximum of 7.9 (S.U. III) (Fig. 3.5). ACL values ranged between a minimum of 27.2 (S.U. IVd upper) and a maximum of 32.5 (S.U. V), with a notable shift toward lower values in S.U. IVc and S.U. IVd (upper).

3.4.3. δ^2H_{wax}

In the region around Abric del Pastor, a strong negative correlation between monthly precipitation amount and precipitation δ^2H (δ^2H_p) is recorded at two GNIP (Global Network for Isotopes in Precipitation; IAEA/WMO, 2006) stations in Murcia and Valencia (Fig. 3.6). This suggests some degree of influence by the amount effect (Dansgaard, 1964) on regional δ^2H_p values, which in turn may contribute to variability in our δ^2H_{wax} signal.

δ^2H_{wax} was analysed for C₂₉ and C₃₁ n-alkanes extracted from sediments collected through the sequence (Fig. 3.7) (Table 3.2). For nC₂₉, the δ^2H_{wax} range is -129‰ to -170‰. The lowest values of -170‰ and -164‰ are recorded in the Holocene sediments from S.U. I. A trend towards low values is also recorded in the uppermost part of S.U. IVd and in S.U. IVc, at -152‰ and -153‰ respectively. Through the rest of the sequence values fluctuate between -129‰ and -148‰. δ^2H_{wax} values for nC₃₁ are generally lower than those obtained for nC₂₉ ranging from -137‰ to -174‰. Overall, however, both sets of values have a similar degree of variation and follow a similar trend.

Figure 3.6 Seasonal cycle of precipitation amount (grey bars) and $\delta^2\text{H}_p$ (black squares) for GNIP stations (IAEA/WMO, 2006) in Murcia (n=11, 2000 – 2010) and Valencia, Spain (n=16, 2000 – 2015).

3.4.4. $\delta^{13}\text{C}_{wax}$

$\delta^{13}\text{C}_{wax}$ measurements were analysed for C_{29} and C_{31} *n*-alkanes extracted from sediments collected through the sequence (Fig. 3.7) (Table 3.2). $\delta^{13}\text{C}_{wax}$ values for $n\text{C}_{29}$ ranged between -32.4‰ and -38.0‰, with maximum ^{13}C enrichment in S.U. IVb, where values of -32.4‰ and -32.8‰ were obtained. A similarly high value is recorded in the base of S.U. IVd at -32.5‰. The lowest value of -38.0‰ comes from S.U. IVa. $\delta^{13}\text{C}_{wax}$ values for $n\text{C}_{31}$ are generally lower than those obtained for $n\text{C}_{29}$, ranging between -33.6‰ and -40.3‰. Overall, however, both sets of values have a similar degree of variation and follow a similar trend.

3.4.5. Micromorphology

The samples analysed are generally composed of the same sedimentological and lithological elements, characterised by a locally reworked sandy sediment, with 5-10% subangular to angular fine and medium sand, ~30% subrounded coarse sand and gravel, resulting principally from the mechanical weathering and decay of the fossiliferous quartz-rich limestone rock shelter. The coarse mineral components frequently appear fissured. The sedimentary matrix is composed of micritic calcite which, with notable exceptions in S.U. IVb and IVd, generally occurs in a good state of preservation with few dissolution features. Clay is present only in small quantities, occurring locally as thin coatings, cappings or infilling the interstitial void space. Detailed descriptions of each thin section sample are provided in Appendix 1 (Table 5).

Microfacies types

Below, we outline the microfacies types identified through micromorphological analyses of thin sections by polarised light microscopy. Brief descriptions are included with a representative photomicrograph of each of the primary microfacies types (Fig. 3.8). Similar features and components are recurrent throughout the sequence (Fig. 3.9 and 3.10) but vary considerably in their degree of abundance, reworking or post-depositional alteration.

1. *Microfacies type 1* This microfacies type is characterised by a crumb to granular microstructure which is quite open, lithologically composed of fine and medium sand-sized grains of quartz alongside micritic and micro-sparitic fossiliferous limestone, which occurs in sizes ranging from fine sand to coarse gravel. Morphologically this fraction appears subrounded to rounded. Frost induced fissuring of larger clasts is observed in addition to the presence of platy coarse grains. Dusty clay coatings occur throughout, as well as clay cappings. Frequent components include burned and unburned angular bone fragments and pieces of both massive and fibrous charcoal, ash

rhombs, occasional fat-derived char which occurs as ~0.5-1.5 mm massive black fragments with a vesicular porosity, and rare coprolites. The internal organisation of the components is unsorted. This microfacies type is associated with good preservation of the calcitic fraction.

(a) *Microfacies type 1a* This microfacies type is similar to MF type 1 but with a higher degree subrounding and rounding of the coarse mineral elements, Fe-Mn segregation and the presence of limpid clay infillings.

(b) *Microfacies type 1b* This microfacies type is similar to MF type 1a but exhibits a poorer preservation of the calcitic matrix.

2. *Microfacies type 2* This microfacies type is characterised by a weakly expressed platy/lenticular microstructure, lithologically very similar to MF type 1. Frost induced fissuring of the coarse mineral fraction is again evident. Components include scattered, unsorted, unburned angular bone fragments and reworked calcitic wood ash. The calcitic fraction is well preserved.

3. *Microfacies type 3* This microfacies type is characterised by a spongy to vughy microstructure dominated by a vesicular or vughy porosity. Lithologically this type is composed of fine and medium sand-sized grains of quartz, although in lower abundance than other MF types, alongside micritic and micro-sparitic fossiliferous limestone ranging from fine sand to coarse gravel. Clasts exhibit a high degree of subrounding and rounding. Components are unsorted and scattered and include reworked charcoal and bone. No calcitic wood ash is observed in this MF type. The calcitic fraction is well preserved.

4. *Microfacies type 4* This microfacies type is characterised by a massive microstructure with low porosity, and a lithology of fine and medium sand-sized grains of quartz alongside micritic and micro-sparitic fossiliferous limestone ranging in size from fine sand to coarse gravel. Clasts occur as sub-angular to angular. Cryofeatures observed in the other MF types are not as evident here. Components include reworked calcitic ash rhombs and angular unburned bone fragments. The calcitic fraction is well preserved.

(a) *Microfacies type 4a* This microfacies type is similar to MF type 4 but with subrounded to rounded coarse mineral elements and frost induced fissuring of the coarse grains.

Figure 3.8 Photomicrographs of primary microfacies types (scale 500µm) (a) MF type 1 (b) MF type 2 (c) MF Type 3 (d) MF Type 4.

Stratigraphic description

S.U. I

This unit is characterised microscopically by MF type 1. The microstructure is crumb to granular with coarse sand and gravel occurring as subrounded to rounded. Organisation of the components is unsorted with a high porosity generated by channels due to root bioturbation. The matrix has a dusty appearance owing to the presence of silt-sized organic matter (humified or carbonised plant cells). Terrestrial snail shell, charcoal, bone fragments and coprolites were identified throughout. Abundant dispersed faecal spherulites were also identified in the uppermost part of this unit.

S.U. II

This unit is characterised mainly by MF type 4 but with isolated zones more closely resembling MF type 1. It exhibits a slight increase in the relative proportion of fine and medium sized quartz sand. Medium and coarse limestone gravel is in a poorer state of preservation than in other units. Gravel-sized clasts frequently exhibit dissolution cavities with rounded edges and dusty clay coatings. Components include angular bone fragments, both burned and unburned, and calcitic wood ash likely resulting from a reworked combustion feature in this unit.

S.U. III

This unit, which is composed of a thin cemented carbonate crust yielding very few archaeological remains, was represented in a single thin section, characterised by MF type 1. Components include bone fragments and rare faecal spherulites.

S.U. IVa-g

Subunit IVa is captured in two thin section samples and is predominantly characterised by the massive microstructure exhibited by MF type 4a, but also containing MF type 1a and MF type

2. The coarse mineral fraction generally occurs as subrounded to rounded and frequently fissured. Components include ash and frequent bone fragments.

Subunit IVb comprises MF type 1b and MF type 3 with a crumb/granular to vughy microstructure. The calcitic matrix within this subunit shows slight dissolution and a porosity with a horizontal arrangement, indicative of cryoturbation. This subunit also contains a lower proportion of gravel relative to the other subunits within S.U IV. The medium and coarse gravel in subunit IVb is also more notably angular, regularly occurring with a lenticular or platy morphology, typical of frost affected sediments. Impregnation of iron oxides is also frequent and occurs both in the matrix and as fine silt sized nodules. The components are very similar to IVa.

Subunit IVc, which is a roof collapse deposit composed of boulders and large angular cobbles, due to the absence of fine material has not been included in the micromorphological study.

Subunit IVd is characterised microscopically by MF type 1a and MF type 3, with a crumb/granular to spongy microstructure. A slightly higher proportion of gravel is recorded in this subunit relative to the other subunits within S.U IV. Again, clasts with a platy morphology are frequent. Dusty clay cappings and fissuring of clasts may be further evidence of mild cryoturbation. Components are similar to IVa and IVb but occur in higher abundances.

Subunits IVe and IVf are represented in two thin sections, characterised by MF type 1 and MF type 1a, with an open crumb to granular microstructure. Well-rounded clasts, fissuring and clay cappings are frequent. Similar to the other subunits in S.U. IV, components include bone fragments, reworked ash and charcoal.

Subunit IVg is represented in three thin sections and is characterised by MF type 1 with an open crumb to granular microstructure. A higher proportion of gravel occurs in this subunit

relative to the overlying subunits. Fe and Mn impregnation features were also identified. Anthropogenic components, such as ash or charcoal, are greatly reduced in quantity within this subunit.

S.U. V

This unit is represented in a single thin section characterised by MF type 1. Lithologically this unit is very similar to S.U IVa with a calcitic matrix and an open crumb to granular microstructure. The matrix is slightly permeated by iron oxides and clay coatings. Components include rare charcoal and bone fragments.

S.U. VI

This unit is characterised by MF type 1 with an open crumb to granular microstructure which is locally compacted. Corroded and fissured clasts in this unit are similar to those recorded in S.U II. Anthropogenic components include burned bone, charcoal, calcitic wood ash and fat-derived char. These occur in much greater abundances than other units. Faecal spherulites are recorded here mixed with reworked combustion residues. Dusty clay coatings and infillings are common. Needle fibre calcite is also recorded here in-filling the interstitial pore space.

3.4.6. Anthracological remains

Anthracological data from Abric del Pastor has been partially published in previous works. Here, anthracological data from S.U. IVc, IVd1, IVd2 (Vidal-Matutano et al., 2015) and S.U. IVd3 (Vidal-Matutano et al., 2017) is presented together with new anthracological data from S.U. IVd4 and S.U. IVd5 (Table 3.3). The scattered charcoal assemblages analysed from units IVc and IVd (IVd1-5) at Abric del Pastor include a total of 957 charcoal fragments and at least

19 taxa have been identified. Despite the small size of most of the wood charcoal remains (1 – 2 mm) and its scarcity in some units, a high variety of taxa indicating the presence of several plant formations in the surroundings can be inferred. Charcoal data from IVd2 and IVd3 has been unified here as data for each unit was not statistically representative (< 100 remains).

Table 3.3 New charcoal data from Abric del Pastor (IVd 4 and IVd5), presented here with S.U. IVc, IVd1, IVd2 (Vidal-Matutano et al., 2015) and S.U. IVd3 (Vidal-Matutano et al., 2017). Note that data from IVd2 and IVd3 are joined here because the total number of wood charcoal fragments for each unit is not statistically representative.

The most representative taxa throughout S.U. IV from Abric del Pastor is *Juniperus* sp. (juniper) together with xeric taxa (Euphorbiaceae, *Ephedra* sp., Cistaceae) (Fig. 3.11). This overall pattern is seen throughout S.U. IVd and IVc (values of 36 – 58%). Values from *Pinus nigra-sylvestris* (black-scots pine) suggest a clear trend decreasing from 29% (S.U. IVd5) to 1% (S.U. IVc). In addition to this, Mediterranean mixed forest taxa including evergreen and deciduous

Quercus (oaks), *Pistacia* sp. (terebinth), *Rosa* sp. (rose), *Prunus* sp. or Maloideae (Rosaceae family) are abundant throughout IVd4 - IVc (38 – 49%). Notably lower proportions of these taxa are, however, recorded in IVd5 (12%). Finally, riverine taxa such as Ulmaceae (the elm family), *Salix-Populus* (willow-poplar) and *Fraxinus* sp. (ash) are present in small amounts (values < 7%). We infer two distinct anthracological phases from the analysed remains (AP-1 and AP-2). Phasing is a preliminary assessment of the data which relies on grouping analytical units to infer periods of distinct environmental conditions.

Figure 3.11 Anthracological data (main plant formations) from Abric del Pastor (IVc – IVd5).

3.4.7. Microvertebrate study (S.U.IVd)

The small vertebrate assemblage from the S.U. IVd contains 295 dental and bone remains that correspond to 33 individuals. The faunal list of this unit contains 3 rodents (*Microtus cabrerae*, *Eliomys quercinus* and *Apodemus sylvaticus*), 1 insectivore (*Crociodura* gr. *russula-gueldenstaedtii*), 1 anuran (*Pelodytes* sp.), 2 lizards (cf. *Timon lepidus* s. l. and cf. *Podarcis* sp.) and 3 snakes (Colubridae indet., *Coronella girondica* and Viperidae indet.) (Appendix 1 Figure 2). The studied assemblage is characterised by the dominance of *Apodemus sylvaticus* (MNI=15), followed by cf. *Podarcis* sp. (MNI=8), *Eliomys quercinus* (MNI=3) and *Microtus cabrerae*, *Crociodura* gr. *russula-gueldenstaedtii*, *Pelodytes* sp., cf. *Timon lepidus* s. l., Colubridae indet., *Coronella girondica* and Viperidae indet. (MNI=1) (Table 3.4).

Taxon	NISP	NMI	%	OD	OH	OWo	Wo	R	W
<i>Microtus cabrerae</i>	6	1	3.03	0	0.50	0.50	0.00	0.00	0.00

Viperidae indet.	1	1	3.03	-	-	-	-	-	-
Total	200	33	100	4	22	47	23	4	0

Table 3.4 Number of Identified Specimens (NISP), Minimum Number of Individuals (NMI) and percentage of representation (%) of small vertebrates from the Unit IVd from Abric del Pastor. Distribution by habitat: **OWo**: Open Woodland, **Wo**: Woodland/Edge-woodland, **OD**: Open Dry, **OH**: Open Humid, **Wa**: Water and **R**: Rocky. Those species in open nomenclature indicate that these taxa could not be classified to the specific habitat level (dashes).

Palaeoecological reconstruction using the MER method indicates a MAT slightly lower than present conditions (-1.48 °C) (Table 3.5). Other climatic parameters such as MTC (-1.05 °C) and MTW (-0.78 °C) point to a cooler climate with precipitation values ranging from 411 mm to 837 mm (MAP 624.13 mm). As only generalist species have been included in the reconstruction, the entire range of possible values should be considered.

	Mean	SD	Max.	Min.	Δ	Alcoy
MAT	12.22	2.85	18.3	-0.2	-1.48	13.7
MTC	0.65	2.88	8.4	-11.4	-1.05	1.7
MTW	27.72	3.47	35.9	11.8	-0.78	28.5
MAP	624.13	212.92	1586	220	81.83	542.3
PWM	77.72	26.25	251	32	3.42	74.3
PDM	23.02	16.09	101.0	0.0	7.82	15.2

Table 3.5 Values of climatic parameters in the region around Alcoy today based on Hijmans et al. (2005) and those obtained through the MER method from the microvertebrate assemblage of S.U. IVd. SD= standard deviation; Max.= maximum; Min.= minimum; Δ= difference with present day conditions. MAT= mean annual temperature; MTC= minimum temperature of the coldest month; MTW= maximum temperature of the warmest month; MAP= mean annual precipitation; PWM= precipitation of wettest month; PDM= precipitation of driest month.

3.4.8. Macrofaunal study (S.U. IVd)

A total of 476 faunal remains has been analysed for this study, 46% of which have been taxonomically determined. Artiodactyls, composed at species level by *Bos primigenius*, *Capra pyrenaica* and *Cervus elaphus*, are the most frequent group among ungulates (73 NR), while perissodactyls are represented only by *Equus ferus* (1 NR). Testudines are the taxonomic category with the greatest number of identified remains in the assemblage (129 NR), all attributed to *Testudo hermanni*. Few remains of rabbit (*Oryctolagus cuniculus*, 8 NR), undetermined birds (2 NR) and small carnivore (1 NR) have also been recorded. The remaining 54% of the assemblage has not been determined taxonomically but can be associated with a weight size category. Medium size is the most abundant category (76 NR), followed by mall (23 NR), very small (5 NR) and large (2). A total of 142 NR could not be determined (Table 3.6).

Taxa	NISP / NR	MNE	MNI
Artiodactyla	8	7	-
<i>Bos primigenius</i>	2	2	1
Caprinae	16	16	2
<i>Capra pyrenaica</i>	28	23	2
Cervidae	5	2	1
<i>Cervus elaphus</i>	14	9	3
<i>Equus ferus</i>	1	1	1

Firmado por: Rory Connolly . UNIVERSIDAD DE LA LAGUNA	Fecha: 17/02/2021 14:01:27
Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

The fragmentation rate is high, with most of the remains measuring < 2 cm in length. Diagenetic alterations were observed throughout the assemblage, with a total of 574 surface damage features identified: concretions (42%), manganese oxide staining (29%), root-marks (15%), corrosion (8%), weathering (5%) and gnaw marks (1%). The skeletal material contains a high quantity of cranial remains, mainly in the form of isolated teeth of *Bos primigenius* and *Capra pyrenaica*, while long bone fragments occur more frequently among *Cervus elaphus*. In the case of tortoise, backplate fragments and plastron are relatively abundant. Conservation analysis by bone density shows a statistically significant positive correlation ($p < 0.05$) in wild goat (0.66) and cervids (0.45), demonstrating an important bias in part of the assemblage. For this reason, utility indices were not applied.

A total of 184 old fractures (fresh and dry) have been identified. They are mainly present in the long bones of ungulates, in the medium-weight size category and to a minor extent in cranial and coxal fragments, scapulae ribs, and a small quantity of tortoise plates. A large proportion of fresh fractures can be clearly linked to anthropogenic activity. See Appendix 1 for additional taphonomic data and information on anthropogenic surface alterations.

Our bioclimatic component calculations (Appendix 1 Figure 4) suggest that the most probable biome for the Abric del Pastor Unit IVd faunal assemblage is Type IV (Mediterranean) (Table 3.7).

3.5. Discussion

Leaf waxes derived from terrestrial higher plants are the predominant source of long-chain length *n*-alkanes (nC₂₇– nC₃₅) at Abric del Pastor. Although long-chain homologues (nC₂₇– nC₃₅) derived from higher plants dominate through most of the sequence, sediment samples collected from S.U. IVd and S.U. IVc yielded *n*-alkane distributions with proportionally increased concentrations of mid-chain length homologues (nC₁₈ to C₂₆) which do not display a strong odd-over-even predominance. Although microbial degradation can alter the chain length distribution of *n*-alkanes (Brittingham et al., 2017), a more likely explanation here may be the incorporation of charred biomass related to anthropogenic combustion activities. Although care was taken during sampling to avoid thermally altered sediments, dispersed ash, charcoal and burned bone are recorded elsewhere in these units at the microstratigraphic scale. Furthermore, at least eight discreet combustion features have been recorded during the excavation S.U. IVd, more than in any other unit (Mallol et al., 2019). Studies elsewhere have demonstrated the effects of thermal degradation on *n*-alkane preservation and distributions (Eckmeier and Wiesenberg, 2009; Wiesenberg et al., 2009; Diefendorf et al., 2015b; Wang et al., 2017; Jambriña-Enríquez et al., 2018). With increasing temperatures, there is a decrease in chain length and a modification of the carbon preference from odd to even homologues, lowering ACL and CPI values. The *n*-alkane distributions and observed co-variance of ACL and CPI in S.U. IVd and IVc could therefore be explained by the effects of anthropogenic fire.

$\delta^{13}\text{C}_{\text{wax}}$ values are within the expected limits for a predominant contribution from C3 plants (Ficken et al., 1998). Through the entire sequence, there is a range of up to 5.6‰ (nC₂₉) and 6.7‰ (nC₃₁) for carbon isotope values, and up to 41‰ (nC₂₉) and 37‰ (nC₃₁) for hydrogen isotope values. $\delta^{13}\text{C}_{\text{wax}}$ decreases from -32.5‰ to -34.9‰ (nC₂₉) and -34.1‰ to -35.9‰ (nC₃₁) between the base and the uppermost part of S.U. IVd, while $\delta^2\text{H}_{\text{wax}}$ decreases from -136‰ to -152‰ (nC₂₉), and from -149‰ to -159‰ (nC₃₁). Although thermal alteration may have contributed to the observed variability (Weisenberg et al., 2009), notably in S.U. Numerous factors likely influence IVd and IVc, $\delta^{13}\text{C}_{\text{wax}}$ and $\delta^2\text{H}_{\text{wax}}$ values through the sequence. Water availability, temperature changes and specific plant attributes can affect fractionation of carbon isotopes by plants during CO₂ uptake and fixation (Δ_{leaf}) (Kaplan et al., 2002; Diefendorf and Freimuth, 2017). Diefendorf et al. (2010) have demonstrated that MAP is a strong predictor of Δ_{leaf} , although microclimate and ecosystem structure factors are also likely to influence $\delta^{13}\text{C}_{\text{wax}}$. Precipitation $\delta^2\text{H}$, evapotranspiration and vegetation type are considered direct controls $\delta^2\text{H}_{\text{wax}}$ values, although other environmental and physiological variables can exert secondary controls (Sachse et al., 2006, 2009, 2012; Liu and Yang, 2008; Liu and An, 2018). Changes in moisture source (Z. Liu et al., 2008; Tipple et al., 2015) or fluctuations in the intensity of the North Atlantic Oscillation (NAO) could play a role in determining precipitation patterns and $\delta^2\text{H}$ values (Muñoz-Díaz and Rodrigo, 2004; Brittingham et al., 2019), explaining some of the variability observed through the sequence at Abric del Pastor. North Atlantic dynamics have been shown to play a significant role in the isotopic composition and variability of precipitation (Benetti et al., 2017). These effects have been recorded elsewhere in the Iberian Peninsula (Jambrina-Enríguez et al., 2017).

A negative correlation between monthly precipitation amount and precipitation $\delta^2\text{H}$ recorded at GNIP (Global Network for Isotopes in Precipitation; IAEA/WMO 2006) stations in Murcia and Valencia suggests that regional $\delta^2\text{H}_p$ values may be influenced to some extent by

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

precipitation amount. Temperature is also likely to have been a significant factor, however, as this plays a role in governing soil water evaporation and leaf transpiration, which in turn affects the primary signal (Sachse et al., 2012; Kahmen et al., 2013; Wang et al., 2016). Water availability is an important control on $\delta^{13}\text{C}$ in C3 plants, which has also previously been shown in certain cases to positively correlate with MAP and relative humidity (RH) (Farquhar et al., 1989; Diefendorf et al., 2010; Garcin et al., 2014; Diefendorf and Freimuth, 2017). Co-varying trends between $\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$ through the sequence at Abric del Pastor could therefore be linked to the combined effects of changes in moisture source, precipitation amount and fluctuations in temperature and evaporative stress.

Evidence of generally cool conditions throughout the sequence are recorded at the microstratigraphic level by the occurrence of weakly lenticular and granular microstructures, in addition to features such as soil cappings, and frequent platy or fissured clasts characteristic of cyclical freeze-thaw processes (Vliet-Lanoë, 2010). The sequence is generally composed of laterally discontinuous sands and gravels derived from the collapse and disintegration of the limestone conglomerate which makes up the rock shelter. Faecal spherulites recorded in S.U. I may be linked to the presence of goats at the site in relatively recent times. In addition to input of fresh leaves from the modern trees and vegetation immediately adjacent to the site, this probably contributes to the elevated TOC values in S.U. I. Other sources may include the frequent occurrence of fresh root-derived OM which has been observed in several thin sections. This highlights the effects of active bioturbation, although, it should be noted that this does not uniformly affect entire the sequence, being more intense in the uppermost units (S.U. I - IVa). Good preservation of the calcitic matrix, sedimentary components, and anthropogenic material throughout most of the sequence signal generally high rates of sedimentation. Indicators of slower sedimentation rates, increased surface exposure and the presence of moisture also occur, however, in the form of redoximorphic features and instances where it is evident that the

calclitic matrix has been affected by dissolution processes. This is observed in S.U. IVd, for instance, and might partially explain the degree of thermal degradation affecting *n*-alkane distributions as slower sedimentary rates produce a palimpsest effect with the concentration and superimposition of materials related to successive combustion events (Bailey, 2007; Machado et al., 2015). The occurrence of textural contrasts and sharp contacts between depositional facies suggest sedimentary accretion at the site is dynamic and responsive to external processes, most likely linked to shifting environmental conditions.

Cool temperatures are also implied by the charcoal assemblage from S.U. IVc and IVd which shows a predominance of juniper (> 50% in some subunits) relative to pine, coherent with the establishment of a cold climate during which heliophilous, drought-tolerant plants progressively developed, accompanied by a decrease in temperatures throughout the Iberian Peninsula (Sánchez-Goñi et al., 1999). Our reconstruction points to dry or semi-arid supramediterranean conditions (MAT of 8 – 13 °C, -4 °C and MAP of 200 – 600 mm, -80 mm), which is congruent with the observed $\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$ values if we accept that temperature and evaporative stress are the dominant controls. Indeed, juniper species show great resistance to changes in temperature and humidity, being physiologically adapted to stress tolerance with low demands in terms of soil (Costa et al., 2005). The homogenous anatomical structure of *Juniperus* does not allow for the discrimination of the species gathered, which could hypothetically include thermophilous species (*J. oxcedrus*, *J. phoenicea*) or cryophilous ones (*J. communis*, *J. thurifera*, *J. sabina*), whose present-day range covers from thermo-Mediterranean to supra-Mediterranean bioclimatic belts together with dry or semi-arid conditions (Costa et al. 2005). However, carpological data from El Salt, a Middle Palaeolithic site located 4 km away from Abric del Pastor, indicate the presence of *Juniperus sabina* (savin juniper) in the region (units VIII – Xa), at least during MIS 3 (Vidal-Matutano et al. 2018a). This taxon is currently abundant in the supra-Mediterranean and oro-Mediterranean bioclimatic belts, above 1100 –

1200 m a.s.l., occurring together with other species of the same genus (*J. communis*, *J. thurifera*) (Rivas-Martínez, 1987; Costa et al. 2005). The absence of thermophilous juniper at Abric del Pastor would be consistent with an anthracological assemblage reflecting a temperature range which is lower than present conditions. The appreciable percentage of mixed forest taxa in those units coinciding with decreasing values of juniper might be explained by the location of the rock shelter in a narrow ravine, where access to several plant formations is possible within a short distance (< 1 km). The presence of these plant formations, with different ecological requirements to juniper, point to the existence of a local vegetation refugium, composed of several biotopes, facilitated by the orography of the narrow ravine.

The current spatial distribution of plant taxa recorded in S.U. IV has been obtained for the Iberian Peninsula, taking into account *Juniperus communis*, *Juniperus ocycedrus*, *Juniperus phoenicea*, *Juniperus thurifera*, *Juniperus sabina*, *Pinus nigra* subsp. *salzmannii*, *Pinus nigra* subsp. *Arnold*, *Taxus baccata*, *Pistacia terebinthus*, *Quercus ilex ballota* and *Quercus faginea*. This is presented here alongside the distribution of the microfaunal species recorded in S.U. IVd (Fig. 3.12). The Javalambre and Gúdar mountain ranges (Teruel) and the eastern Iberian mountain system show the highest proportions of overlapping plant taxa. This mountainous region (1000 – 1500 m a.s.l.) is located at the supramediterranean bioclimatic belt with a MAT of 8 – 10 °C and a MAP of 400 – 600 mm (Rivas-Martínez, 1987). Isolated locations are also highlighted in the Pyrenees and the Central and Betic mountain systems.

Figure 3.12 10 x 10 UTM squares obtained overlapping the distribution areas of the main plant (red squares) and small mammal, reptile and amphibian (black squares) species analysed in this study.

Our palaeoecological reconstruction based on the the microfauna suggests a similar scenario, with generally cooler (MAT -1.48 °C) and possibly drier (411 mm to 837 mm) conditions than present. The Habitat Weighting Method indicates a predominance of open woodland environments (47%) (Appendix 1 Figure 3), which includes woodland margins and forest patches with moderate ground cover, evidenced by the abundance of *Apodemus sylvaticus*. This species is ubiquitous throughout Spain, normally occupying areas with a good shrub or tree cover (Palomo et al., 2007). Woodlands and Open Humid habitats are next most-commonly represented habitat types in S.U. IVd, although values are only approximately half those obtained for Open Woodland habitats, at 23% and 22% respectively. Species linked to rocky environments such as *Eliomys quercinus*, *Pelodytes* sp., *Coronella girondica* and Viperidae indet. are probably explained by the topographic context of the site, near a cliff. The presence of temporary water bodies is indicated by the remains of *Pelodytes* sp., despite appearing in

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

lower proportions. The probable agent responsible for the accumulation of the assemblage, *Bubo bubo*, is a nocturnal raptor widespread throughout Europe and Asia (see Appendix 1). This species depends on a wide range of prey and its associated prey assemblages are taxonomically diverse with a high degree of equitability.

The macrofaunal assemblage from S.U. IVd is characteristic of Mediterranean conditions. Climatic reconstruction based on the CRI model yielded an AAP value of 268 mm, which is consistent with ranges obtained from other proxies. Variation in the proposed temperature values between the different datasets probably reflect the disparate depositional agents responsible for their accumulation and the differing spatial resolutions of the proxies. The taxonomic composition of the assemblage is potentially congruent with either an MIS 5 setting, or a phase of climatic amelioration during MIS 4. As such, the frequent occurrence of Mediterranean tortoise (*Testudo hermanni*) in S.U. IVd is notable. In Pleistocene chronologies, there are few archaeological deposits in the Mediterranean area where *Testudo hermanni* is present during MIS 4, limited to Cova Dalt del Tossal de la Font (MIS5d-4) and Abric del Pastor (Morales and Sanchis, 2009; Sanchis et al., 2015; Mallol et al., 2019). In fact, a recent review of Neanderthal consumption of *Testudo hermanni* in the Iberian Peninsula by Nabais and Zilhão (2019) suggests that the species may have almost completely disappeared from the peninsula at the onset of MIS 4 as a result of over-exploitation. It's presence at Abric del Pastor is in agreement with the anthracological data which suggests that the ravine where the site is located probably acted as a vegetation refugium, providing sufficient tree and shrub cover for this species to thrive, as well as an abundant and diverse source of woody biomass which could be exploited as fuel by Neanderthal groups.

The resolution of the current chronological framework at Abric del Pastor limits the direct comparisons which can be drawn between our sequence and other regional palaeoclimate

records. Nevertheless, our most complete dataset comes from S.U. IVd, which corresponds with an OSL date of 63 kya \pm 5000, implying an MIS 4 or possible late MIS 5 setting. During the period in question, evidence from the upper Tagus Basin suggests the accumulation of significant loess deposits are linked to cool and dry conditions through MIS 4, but perhaps began accumulating as early as late MIS 5 (Wolf et al., 2018). This might point to the development of adverse environmental conditions in the Iberian interior, with decreasing vegetation cover limiting the availability of important resources. In such a scenario, peripheral regions along the Iberian coastline may have been more climatically favourable for Neanderthal groups. Pollen records from Area Longa (Galicia) in the north-west of the peninsula record a stadial vegetation with grassland and heathland through the earliest stages of MIS 4 (Gómez-Orellana et al., 2007; Fletcher et al., 2010), while palynological records from Abric Romaní, in the north-east, record a predominance of steppe vegetation (*Artemisia*) characteristic of generally dry and cold conditions, interspersed by rapid episodic shifts in vegetation structure which led to an increase in grasses (Poaceae) followed by a decline in pines and deciduous oaks (*Quercus*). The presence of *Betula* with *Corylus*, *Viburnum* and Mediterranean taxa, suggest that localised glacial refugia persisted during MIS 4 (Burjachs and Julià, 1994; Biltekin et al., 2019). This is in keeping with the data presented here from Abric del Pastor and taken together could predict similar conditions for MIS 4 throughout the Eastern Iberian Peninsula, pointing to a mosaic scenario with different biotopes shaped by local geographic factors.

3.6. Concluding remarks

Drawing on multiple lines of evidence, we have investigated climatic variability through the sequence at Abric del Pastor. Our data points to a generally cold but variable climate through the Pleistocene part of the sequence, as evidenced by the persistent presence of cryoturbation features in our micromorphological samples. *n*-Alkane distributions and co-varying CPI and

ACL values in S.U. IVc and IVd reflect degradation linked to the probable incorporation of charred biomass associated with anthropogenic burning events. This is supported by the archaeological evidence at the macroscopic scale where eight combustion features are recorded in S.U. IVd, as well as at the microstratigraphic scale where combustion residues are linked to microfacies which show signs of slower sedimentary rates. Fluctuations in $\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$ through the sequence can be explained as the combined effects of moisture source changes, regional precipitation amount and changes in atmospheric temperatures. This is consistent with our anthracological analysis of S.U. IVc and IVd which indicates a prevalence of dry to semi-arid supramediterranean conditions (MAT -4°C and MAP of 200 – 600 mm, -80 mm) and our reconstruction based on the small-mammal assemblage (MAT -1.48°C , MAP 411 mm to 837 mm). At this part of the sequence, which corresponds with an OSL date of 63 kya (± 5000 1 σ), we propose a scenario where open dry woodland formations extended throughout the upper reaches of the valley, while Mediterranean mixed forest taxa and riverine species survived within the Barranc del Cinc ravine, a vegetation refugium providing adequate tree cover and ground shrubs to support species such as *Testudo hermanni*, which were exploited for subsistence by Neanderthal groups. The ravine also provided an abundant fuel source in the form of woody biomass. The occupation of the rock shelter may have formed part of a broad subsistence and mobility strategy focused on intra-mountainous valleys or ravines, like the Barranc del Cinc, which are zones of ecological resilience and biodiversity that provide opportunities for the construction of crucial econiches.

Finally, our results demonstrate the utility of a coupled biomolecular and geoarchaeological approach, however, encourage caution for future studies in archaeological contexts where microscopic residues, related to anthropogenic fire for instance, can potentially influence the molecular or isotopic signal. In such cases, soil micromorphology is a powerful tool for

Abstract

Here we present a multiproxy palaeoenvironmental study from Stratigraphic Units VIII – V (upper) at the Middle Palaeolithic site of El Salt (Alcoy, Spain), which hosts a long sequence of Late Pleistocene deposits yielding abundant evidence for recurrent Neanderthal occupations through the course of Marine Isotope Stage 3 (MIS 3). Site formation processes have been reconstructed through the application of soil micromorphology and the sedimentary sequence has been analysed for lipid biomarker *n*-alkane abundances (CPI, ACL, VPD, LAR, *Paq*), compound-specific isotope analysis ($\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$), bulk organic geochemistry (TOC), and pollen/non-pollen palynomorphs. Our results are in line with other regional studies and support previous palaeoecological research at this site which suggests that the cessation of Neanderthal activity in Eastern Iberia *c.* 45 kya coincides with a scenario of widespread aridification.

4.1. Introduction

The disappearance of Neanderthals from the archaeological record *c.* 40 kya, and their subsequent placement by anatomically modern humans (AMH) across Europe, is a defining

Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

characteristic of the Middle to Upper Palaeolithic transition (MUPT), a process widely regarded as amongst the most significant cultural transitions to have occurred in the course of human evolution (Blockley et al., 2008; d'Errico and Sánchez Goñi, 2003; Finlayson et al., 2007; Greenbaum et al., 2018; Mellars, 2004; Morley, 2012; Villa et al., 2018; Villa and Roebroeks, 2014; Zilhao, 2006). There remains, however, considerable debate regarding the extent to which climatic change should be considered a driving factor in this process (Blain et al., 2013; Burke et al., 2014; Defleur and Desclaux, 2019; Finlayson, 2004; Finlayson and Carrión, 2007; Jiménez-Espejo et al., 2007; Müller et al., 2011; Roberts and Bricher, 2018; Sepulchre et al., 2007; Staubwasser et al., 2018; Wakano et al., 2018; Wolf et al., 2018). Owing to its geographical situation and the possible late survival of Neanderthals in this region, the Iberian Peninsula has long been considered a key location for understanding Neanderthal adaptation to climate. It has been suggested that the southern and eastern margins of the peninsula may have provided local refugia with conditions favourable to Neanderthal survival during periods of wider global climatic deterioration (Finlayson et al., 2007; Jennings et al., 2011; Ochando et al., 2019).

The climatic and environmental framework for Iberia during Marine Isotope Stage 3 (MIS 3) (57-29 kya) is largely drawn from off-shore marine cores, peat deposits, and speleothems, while palynological, palaeobotanical and palaeontological material recovered from archaeological contexts has provided an additional source of information (Burjachs et al., 2012; Daura et al., 2017; Esteban et al., 2017; López-García et al., 2014, 2012; Ochando et al., 2019). These records indicate highly variable conditions which fluctuated between extremely cold episodes with occasionally short-lived warm intervals linked to globally significant Heinrich events and Dansgaard-Oeschger (D/O) oscillations (Fletcher et al., 2010; Naughton et al., 2009; Roucoux et al., 2001, 2005; Sánchez Goñi et al., 2008; Sanchez Goñi and Harrison, 2010). Throughout Heinrich events, mean annual precipitation (MAP) in Iberia is estimated to have

been approximately 400 mm less than current values, with winter temperatures between 6 - 13 °C lower. More temperate climate phases, on the other hand, are marked by MAP values between 600 - 800 mm and winter temperatures between 5 - 10 °C, similar to conditions experienced throughout the peninsula today (Cacho et al., 1999; d'Errico and Sánchez Goñi, 2003; Sánchez Goñi et al., 2008). Cold phases with low MAP values resulted in the development of large areas dominated by desert-steppe vegetation which saw a reduction in vegetation cover to less than 25 % of present-day values (d'Errico and Sánchez Goñi, 2003; Sepulchre et al., 2007).

The final phase of Neanderthal demographic collapse has been attributed by some to an episode of abrupt aridification and climatic cooling during Heinrich Event 4 (HE 4) between 39 - 40 kya (Bradtmöller et al., 2012; e.g. d'Errico and Sánchez Goñi, 2003; Mellars, 2006). There is, however, mounting evidence that in several locations the disappearance of Neanderthal groups occurred prior to the onset of HE 4 (Higham et al., 2014; Wood et al., 2013). Here, we combine a range of palaeoenvironmental techniques to investigate a sedimentary sequence from Stratigraphic Units (S.U.) VIII - V (upper) at the Middle Palaeolithic site of El Salt in Eastern Iberia, where a recent TL and OSL dating program has indicated the disappearance of the local Neanderthal population c. 45 kya (Galván et al., 2014).

4.2. Materials and methods

4.2.1. Site background

El Salt (38°41'14" N, 0°30'32" W, 680 a.s.l.) is an open-air Middle Palaeolithic site situated c. 3 km outside the city of Alcoy, immediately south-east of the Sierra de Mariola in a mountainous region of Eastern Iberia's central Mediterranean coast, close to the Serpis and Barxell rivers (Fig. 4.1). Archaeological excavations, which are ongoing since 1986 and led by

a multidisciplinary team from the Universidad de La Laguna, have yielded abundant evidence for recurrent Neanderthal occupation activity between 60.7 ± 8.9 and 45.2 ± 3.4 ka BP (Fagoaga et al., 2018; Galván et al., 2014, 2001; Garralda et al., 2014; Gómez de la Rúa et al., 2010; Leierer et al., 2019; Machado et al., 2017, 2015; Mallol et al., 2013; Rodríguez-Cintas and Cabanes, 2017; Sistiaga et al., 2014; Vidal-Matutano et al., 2018b). Activity areas at the site are concentrated at the base of a 38 m high Palaeocene limestone cliff which is covered by partially active tufa/travertine formation and formed along a thrust fault. Tufa formation is driven by an 80 m episodic waterfall which is fed by the Barxell River and Pou del Barxell spring (806 m a.s.l.), located 3.6 km upstream (Ordóñez et al., 2016). El Salt is today situated in a mesomediterranean bioclimatic belt with MAP values >500 mm and a mean annual temperature (MAT) of 14 °C (Rivas-Martinez, 1987).

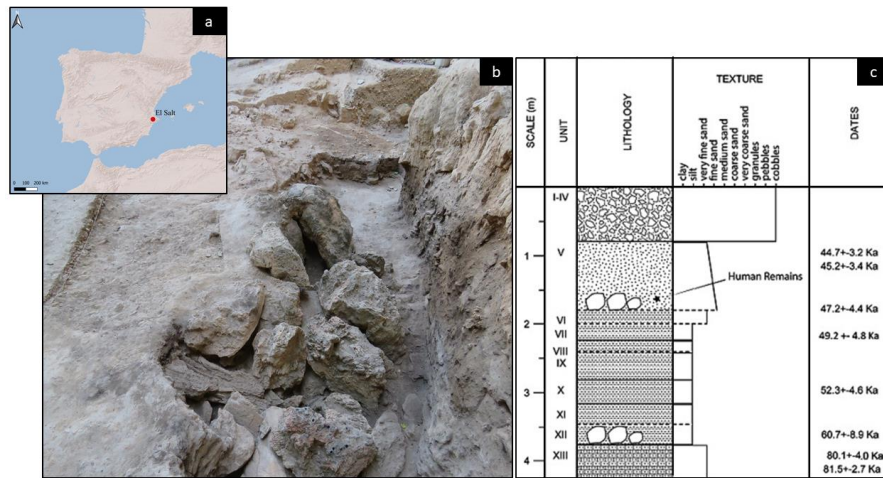

Figure 4.1 El Salt Middle Palaeolithic site: (a) Map showing location of the site on the Iberian Central Mediterranean coast; (b) Photograph of site excavation surface. Note the large limestone blocks from the roof collapse; (c) Stratigraphic log showing the position of the recovered human remains and absolute dates (after Galván et al., 2014).

The sequence hosts a 6.3 m thick deposit which has been divided into thirteen primary stratigraphic units (S.U. XIII - S.U. I), broadly grouped according to their macroscopic textural characteristics and their archaeological content (Galván et al., 2014): S.U. XIII at the base of the sequence is an archaeologically sterile travertine platform. Dating by U-Th places this between 81.5 ± 2.7 kya and 80.1 ± 4 kya (Fumanal, 1994). S.U. XII - S.U. IX (~1.5m) is formed by horizontally bedded fine geogenic sands overlaying a clastic facies at the base of this segment, which contains a number of considerably large blocks, pointing to a significant collapse event. Archaeological material is abundant in this part of the sequence, being particularly concentrated in S.U. X, which yielded a large number of simple flat combustion structures with associated faunal and lithic assemblages (Leierer et al., 2019; Machado and Pérez, 2015; Mallol et al., 2013). S.U. VIII to S.U. V (lower) (1.5 - 2.8 m) is composed of horizontally bedded geogenic sands, S.U. VI is sealed by large blocks which suggest another significant collapse event. The concentration of archaeological material in this part of the sequence is marked by a notable decrease both laterally and vertically. S.U. V (upper) (~0.5 m) is characterised by sandy silt with medium to large gravel in the top 20 cm. Archaeologically

only two small flint blades, occasional debitage and a single combustion feature are recorded here. S.U. IV - S.U. I (~1.3 m) consist of irregular beds of gravel and cobbles within a silty clayey matrix. Stratification is evidently quite disturbed with Neolithic pottery having been recovered commingled with late Upper Palaeolithic, Epipalaeolithic and Mesolithic materials.

A previous study of the small mammal assemblage recovered from S.U. Xb (52.3 ± 4.6 ka) indicated relatively cold and humid conditions in an environment composed predominantly of open woodlands and a patchwork of dry and humid meadows (Fagoaga et al., 2018), while anthracological and carpological analyses of plant remains recovered from S.U. Xb, Xa, IX, and XIII (52.3 ± 4.6 ka to 49.2 ± 4.8 ka) pointed to a predominance of sub-humid supra-Mediterranean conditions (MAT 8–13 °C and MAP 600–1000 mm) (Vidal-Matutano et al., 2018b). A more recent study of the small mammal assemblage recovered from S.U. V (upper) (45.2 ± 3.4 ka to 44.7 ± 3.2 ka) suggests an arid climatic setting at this part of the sequence, around the time of the final Neanderthal occupations at the site (Fagoaga et al., 2019). Here, we focus on S.U.'s VIII – V (upper) (Fig. 4.2).

Figure 4.2 Sediment profiles mentioned in this study: (a) Photograph of P.13 with stratigraphic units highlighted and labelled; (b) Photograph of P.20 and P.20a which comprise S.U. V (upper). Inset shows a close-up of the fine sediments recorded at this part of the sequence; (c) Site orthophotograph with profiles highlighted and numbered.

4.2.2. Soil micromorphology

Intact, oriented blocks of sediment from S.U. VIII - S.U. V (upper) were extracted from selected profiles (P.1, P.3, P.13, P.21 and P.24) for micromorphological analysis. The goal of applying this technique was to characterise site formation processes and the local sedimentary context, identifying features at the microstratigraphic scale which may be linked to particular environmental conditions.

Samples were oven-dried at 60 °C for 48 hours and subsequently impregnated with a mixture of polyester resin (Palatal strained resin UN1866, TNK composites), styrene (Styrene monomer [CAS: 100-42-5] UN2055, TNK composites) and catalyser (Luperox [CAS: 78-93-3], TNK composites) in a 7:3:0.1 ratio. After hardening, a Euro-Shatal M31100 radial saw was used to cut the blocks into 1 cm-thick slabs. Samples were sent to Spectrum Petrographics (Vancouver, WA, USA) for thin section manufacture (7 cm x 5 cm x 30 µm) and micromorphological analyses were carried out using a Nikon E200 polarising microscope. Descriptions follow the standard guidelines set out in Stoops (2003) and Nicosia and Stoops (2017).

4.2.3. Total Organic Carbon (TOC)

TOC (%) was analysed with a LECO SC 144DR furnace at the Instituto Pirenaico de Ecología (IPE-CSIC), Spain.

4.2.4. Lipid biomarker analysis (n-alkanes)

Sediment samples (5-10 g) from S.U. VIII – V (upper) were collected from P.13, P.20, P.20a, and P.21 at a 1-5 cm interval. The black layers (BL) at the base of S.U. VIII were not sampled for lipids to avoid anthropogenic combustion residues. Lipid biomarker analyses were conducted at the Archaeological Micromorphology and Biomarkers Laboratory (AMBI), Universidad de La Laguna, Tenerife.

Samples were oven-dried at a temperature of 60 °C for 24 h prior to extraction. Extraction of the target alkanes from sediments was carried out following the optimised QuEChERS method set out by Herrera-Herrera et al. (2020) based on the original methodology proposed by Anastassiades et al. (2003). 5 g of sediment was transferred to a 50 mL PTFE tube and one spherical glass ball was included. 10 mL of DCM as extraction solvent was added and the

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

mixture was manually shaken for 1 min. IS was added (1 µL 400 mg/L) and the tube was again manually agitated for 30 s. 4 g of MgSO₄ and 1 g of NaCl were subsequently added. Manual agitation was again carried out for a duration of 1 min and the mixture was centrifuged at 4700 r.p.m. for 5 min using a Mega Star 1.6 from VWR International (Barcelona, Spain). The supernatant (approx. 6 mL) was then transferred to another 50 mL PTFE tube containing 150 mg of MgSO₄ and 25 mg of PSA (clean-up sorbent). This was manually agitated for 30 s and centrifuged at 4700 r.p.m. for 5 min. The supernatant was collected and evaporated under a nitrogen flow using an Organomation evaporator (Massachusetts, USA). The residue was reconstituted in 50 µL of hexane prior to injection in the GC-MS system.

Identification of individual compounds was carried out by comparison of retention times and mass spectra to those of reference compounds (mix C₈-C₄₀ and 5α-androstane, Supelco) and mass spectral library databases (NIST). Quantification of concentrations was achieved using calibration curves obtained which plot the ratio Area/Area_{IS} versus the concentration of reference compounds. Correlation coefficients for each sample were higher than 0.995. Concentration is expressed here in terms of µg of individual compound per gram of dry sample (µg gds⁻¹). Concentration of *n*-alkanes are calculated using calibration curves following the recommendations of Herrera-Herrera et al. (2020).

The Average Chain Length (ACL) was calculated following Poynter et al. (1989) and Freeman and Pancost (2013) using the C₁₈ - C₃₅ interval: $ACL_{18-35} = \Sigma(C_i \times [C_i]) / \Sigma[C_i]; 18 \leq i \leq 35$

The mean annual Vapour Pressure Deficit (VPD_{av}) was calculated following Eley and Hren (2018): $VPD = 1.3125 - \sqrt{14.1208 - 0.4629 \times ACL}$

The Carbon Preference Index (CPI) value (C₁₈ to C₃₅) follows the equation set out in Bray and Evans (1961) and Cooper and Bray (1963): $CPI_{25-33} = [(\Sigma C_{25-33\text{odd}} / \Sigma C_{24-32\text{even}}) + (\Sigma C_{25-33\text{odd}} / \Sigma C_{26-34\text{even}})] \times 0.5$

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

Values > 1 denote an odd over even preference (OEP) while values < 1 are indicative of an even over odd preference (EOP).

The Paq index was calculated following Ficken et al. (2000): $Paq = (C_{23} + C_{25}) / (C_{23} + C_{25} + C_{29} + C_{31})$

The value [Ci] represents the *n*-alkane concentration where i is the number of carbon atoms.

The relative contribution of *n*-alkanes C₂₉ and C₃₁ through the sequence was assessed using long-chain *n*-alkane ratios (LARs): $C_{29} / (C_{29} + C_{31})$

4.2.5. Compound specific isotope analysis (CSIA)

Isotope analysis of individual *n*-alkanes was carried out using a Thermo Scientific Isotope Ratio Mass Spectrometer Delta V Advantage coupled to a GC Trace1310 through a Conflo IV interface with a temperature converter GC Isolink II. A Trace Gold 5-MS (Thermo Scientific) fused silica capillary column ((5%-diphenyl)-dimethylpolysiloxane, 30 m length x 0.25 mm i.d., 0.25 µm film thickness) was used. The helium carrier gas flow rate set was set at 1.5 mL/min. All measurements were carried out in triplicate. Isodat 3.0 software (Thermo Scientific) was employed for data acquisition and processing.

Here, carbon ($\delta^{13}C$) and hydrogen (δ^2H) isotope values are reported for *n*-alkanes C₂₉ and C₃₁. Samples were injected using a Programmed Temperature Vaporising injector (PTV) in splitless mode. Temperatures initially increased from 60 °C to 79 °C (held 30 s, rate 10 °C/min) and then to 325 °C (held 3 min, rate 10 °C/s) and finally to 350 °C (held 3 min, rate 14 °C/s). For the GC oven, a 2 min isothermal period at 70 °C increasing to 140 °C (held 2 min, rate 12 °C/min) was followed by an increase to 320 °C (held 15 min, rate 3 °C/min). The high-temperature conversion (HTC) oven was maintained at 1000 °C during carbon isotope analysis and 1420 °C during hydrogen isotope analysis. Values were normalised to the Vienna Pee Dee

Belemnite (VPDB) scale ($\delta^{13}\text{C}$) and Vienna Standard Mean Ocean Water (VSMOW) scale ($\delta^2\text{H}$) using an *n*-alkane Schimmelmann type A6 mixture ($n\text{C}_{16}$ to $n\text{C}_{30}$) of known isotopic composition (Arndt Schimmelmann; Biogeochemical Laboratories, Indiana University). Reproducibility was greater than $\pm 0.5\%$ for carbon isotope measurements and $\pm 5.0\%$ for hydrogen isotope measurements.

4.2.6. Pollen

A total of 42 samples were collected from four different profiles: 28 from P.13, 5 from P.20, 6 from P.20a, and 4 from P.21. P.13 was sampled at 1-5 cm interval, while the other profiles were sampled every 10 cm.

Samples were chemically treated according to the modified Goeury and de Beaulieu (1979) methodology described by Burjachs et al. (2003). The treatment includes hydrochloric acid (HCl) to remove carbonates, NaOH digestion to remove humic acids, Thoulet heavy liquid (2–2.1 cm³/g) for densimetric extraction of palynomorphs, and hydrofluoric acid (HF) to destroy glass-fibre filters. Palynomorphs were counted in an optical microscope at 40x and 1000x to a minimum pollen sum of 150 terrestrial pollen grains. They were identified using published keys (e.g. Moore et al., 1991; Reille, 1992, 1995) and a modern pollen reference collection. Palynological diagrams were plotted using TiliaIT software, version 2.0.41 (Grimm, 1991–2015). General pollen results are expressed in percentages, as well as taxonomic variability. They are divided into arboreal pollen (AP) and non-arboreal pollen (NAP) to conform to the European Pollen Database (EPD) standard (<http://www.europeanpollendatabase.net/>). Different pollen zones are defined using a stratigraphically constrained cluster analysis (CONISS) (Grimm, 1987). Although cluster was included, zones were not highlighted in the diagram to focus instead on the differences between the different stratigraphic units.

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

To plot a diagram, it was necessary to sum some components. The basis sum includes the arboreal and non-arboreal elements (AP/NAP). Some taxa are usually excluded from this sum because, due to factors in their production and dispersion, they are overrepresented and can distort our results. In archaeological deposits, and more specifically in caves and rock-shelters, the presence of entomophilous pollen grains can be related to human or animal activity (González Sampéris, 1998); one well-known example is Asteraceae (Bottema, 1975; Carrión, 1992; Carrión and Munuera, 1997). Sometimes, taxa may occur in lumps, and it is considered that a significant portion of these pollen grains may be buried by insects (Bottema, 1975; Davis and Buchmann, 1994). For these reasons, the following taxa were excluded from our basis sum and included in the total pollen sum: Cyperaceae, Asteraceae (Cardueae, Asteroideae, Liguliflorae type, and *Centaurea*) Apiaceae, and Liliaceae.

4.2.7. Non-Pollen Palynomorphs (NPPs)

Non-pollen palynomorphs (NPPs) are microfossils included in sediments that are processed for palynological analysis. They are sub-fossil remains of a great variety of organisms that can be sensitive to various ecological parameters or to human presence (Miola, 2012). Although some NPPs have been identified and related to specific conditions, the origins of most of them remain unknown. NPPs were counted under the microscope alongside the identification of pollen grains. Diagrams were plotted using TiliaIT software, version 2.0.41 (Grimm, 1991–2015). Different zones were defined using a stratigraphically constrained cluster analysis (CONISS) (Grimm, 1987). As before, zones were not marked in the diagram to better highlight the differences between archaeological levels.

4.3. Results

4.3.1. Soil micromorphology

Samples are generally composed of similar sedimentological and lithological components, although abundances and degree of weathering vary considerably within and between different stratigraphic units. This is represented by an organic-rich heterometric mix of quartz sand, detritic tufa and travertine from an Upper Pleistocene freshwater spring system, as well as micritic peloids and fossiliferous micritic to microsparitic limestone derived from the physical weathering and disaggregation of the local bedrock. Here, we have arranged the lithological fraction into lithology types A, B, B*, C, D and E (Table 4.1) according to the distribution of lithological elements and textural classes. The fine mass throughout the sequence is composed of calcitic-crystallitic clayey silt which is locally decalcified (Fig. 4.3) or undifferentiated and the predominant microstructure throughout is described here as intergrain microaggregate, although locally massive, granular and vughy microstructures are also recorded. The same organic components are ubiquitous throughout the sequence; this includes *Celtis sp.* seed coatings, coprolites (massive and fibrous), guano accumulations, bone fragments, charcoal, flint debitage, calcitic wood ash, fat-derived char, and microfaunal remains (Table 4.2). Detailed descriptions of each thin section sample are provided in Appendix 2.

Table 4.1 Lithology types (LT) present through the sedimentary sequence at El Salt. Textural classes follow the Wentworth scale used for the classification of fine sediment: silt (s, 50 – 2 µm), very fine sand (vfs, 125 – 50 µm), fine sand (fs, 250 – 125 µm), medium sand (ms, 500 – 250 µm), coarse sand (cs, 1000 – 500 µm), very coarse sand (vs, 2000 – 1000 µm), gravel (g, >2000 µm). Key: 1 = rare/few (0 – 15 %), 2 = common (15 – 50 %), abundant/dominant (>50 %), angular (A), subangular/subrounded (S), rounded (R).

COMPONENT	DESCRIPTION	VIII	VII	VI	V (LOWER)	V (UPPER)
SEED COATINGS	Seed coatings from the <i>Celtis sp.</i> plant are ubiquitous throughout the sequence, ranging from fragments of c. 150 µm to more complete examples over 1 cm. Occasionally fragmented or burned examples occur in association with combustion residues. Previously reported in El Salt S.U. Xb by Mallol et al. (2013), Rodríguez-Cintas et al. (2017), and Vidal-Matutano et al. (2018b).	2S	3S	2S	1S	1S
COPROLITES	Phosphate-rich massive and fibrous coprolites of herbivore origin are recorded in several units through the sequence. Frequently exhibit micrometre-sized plant pseudomorphs. Previously reported in El Salt S.U. Xb by Leierer et al. (2019).	2S	2S	2S	1S	1S
PHOSPHATE	Phosphatic features of the El Salt sequence are predominantly associated with guano (from birds or bats), which is isotropic in XPL and appears in PPL as pale yellow to yellow amorphous concentrations which exhibit a bedded spongy microstructure and vuggy porosity. Phosphatic crusts are also recorded in several units and may indicate prolonged surface exposure and human site abandonment (Karkanas et al., 2017).	3	3	3	2	2
GYPSUM	Authigenic mm-sized gypsum nodules/crystals occur throughout the El Salt sequence but seem to be particularly prevalent in S.U. V (lower and upper). These appear as inclusions within the interstitial void space, although a few gypsum coatings have been recorded. Their presence is consistent with secondary mineral formation linked to repeated cycles of post-depositional dissolution and re-precipitation (Poch et al., 2018), although the diagenetic alteration of guano may account for a small amount of the observed gypsum (Goldberg et al., 2009; Shaahack-Gross et al., 2004).	1	2	2	3	3
CHARCOAL	Charcoal fragments, typically < 500 µm, are ubiquitous throughout the El Salt sequence, although there is considerable variation in the proportions and spatial organisation both within and between units. In some samples, local concentrations of charcoal fragments appear angular, these are generally associated with anthropogenic combustion features, whereas in other samples, diffusely bedded charcoal fragments interspersed throughout the matrix appear sub-rounded to rounded. Both woody and fibrous charcoal are recorded, although woody charcoal predominates. Through few, the presence of	3A	3A	3A	1S	1S

	finely laminated fibrous charcoal may indicate monocotyledonous plants (Miller and Sievers, 2012; Miller et al., 2013). This is consistent with anthracological analysis conducted on S.U. Xb - VIII by Vidal-Matutano et al. (2018b).					
CHAR	Small fragments, < 300 µm, of char are rare. Where present, these occur as sub-rounded isotropic fragments of massive black glassy material with a vesicular texture. These have previously been recorded in micromorphological samples from El Salt as well as other archaeological contexts containing combustion residues (Leyerer et al., 2019; Goldberg et al., 2009), and are most likely linked to the combustion of animal and plant fats.	-	1S	-	-	-
PHYTOLITHS	Some of the units from El Salt contain numerous phytoliths. These are identified as elongate psilate morphotypes and often appear as clusters, both in anatomical connection and loose. Phytoliths from El Salt have previously been described for S.U. Xb by Rodríguez-Cintas et al. (2017).	2	1	2	1	1
BONE	Bone fragments occur in all samples from the El Salt sequence. These are generally sand to cm-sized pieces predominantly derived from small mammals. Appear as angular to sub-angular/sub-rounded fragments, yellow to white in colour (PPL). In some samples associated with anthropogenic combustion activities, fragments appear burned or calcined. Spatial distribution varies between units, with fragments sometimes appearing to be interspersed chaotically throughout the matrix, and other times appearing to be diffusely bedded.	3S	3S	2S	2S	2S
FLINT MICROFLAKES	Cryptocrystalline flint microflakes of anthropogenic origin are recorded in several units at El Salt. These appear as angular fragments ranging in size from 500 µm to 1 cm and are pale yellow in colour (PPL). Some fragments show moderate weathering and signs of fissuring, which may be related to heating. Similar microflakes have been recorded from El Salt S.U. Xb in association with combustion features, as well as a wide range of other sites (Angelucci, 2010; Leyerer et al., 2019).	-	2A	2A	-	-
ROOF SPALL	In addition to the large limestone boulders that seal S.U. V1, elongated sub-angular to sub-rounded fragments derived from the spalling of material from the Palaeocene limestone cliff and shelter roof are found throughout the sequence. These include fossiliferous limestone, recrystallised tufa, and travertine, and have previously been reported by Mallol et al., (2013) and Leyerer et al., (2019) in S.U. Xb.	2S	2S	2S	1A	1A
ORGANIC PARTICLES (BLACK OM)	Silt to sand-sized particles of finely comminuted, humified organic matter and fibrous organic material is recorded in several units at El Salt, although the abundance varies considerably between units. In all likelihood these materials are the product of natural agents and reflect the remains of decayed plants. Their deposition can be linked to the presence of leaf litter from surrounding vegetation, or alternatively to faunal activity such as nesting birds (Miller et al., 2013). Anthropogenic activity may also account for some of the accumulation of organic particles.	3	2	2	1	1

Table 4.2 Components identified in thin section from micromorphological samples from El Salt. Key: 1 = rare/few (0 – 15 %), 2 = common (15 – 50 %), abundant/dominant (>50 %), angular (A), subangular/subrounded (S), rounded (R).

Figure 4.3 Photomicrographs (XPL, cross-polarised; PPL, plane-polarised) of a sedimentary matrix showing the calcified (a. PPL; b. XPL) and decalcified (c. PPL; d. XPL) groundmass typical of S.U. V and S.U. VIII respectively.

S.U. VIII

S.U. VIII is characterised by lithology types A and C, composed of diffusely bedded, moderately sorted, detrital sand and gravel and decalcified groundmass. The presence of intact and fragmented guano crusts is a recurrent feature in this unit. A thin layer of anatomically connected phytoliths is also identified here, as well as disarticulated phytoliths scattered throughout. Their presence at this part of the sequence is noteworthy as they are typically absent or poorly represented in S.U. V, though it is worth noting that a previous study has shown that phytoliths are a common feature of unit Xb (Rodríguez-Cintas et al., 2017). Charcoal fragments and silt to sand-sized organic particles (black OM) are abundant throughout this unit. Pockets

of phosphate, massive and fibrous coprolites, authigenic gypsum infillings, fragments of bone and shell, *Celtis sp.* seed coatings and flint debitage also occur.

S.U. VII

S.U. VII is lithologically very similar to S.U. VIII, being composed of lithology types A and C. Here, however, the diffusely bedded detrital sand and gravel appears more poorly sorted. This unit is locally bioturbated, as evidenced by the presence of channels and chambers infilled by faecal excrements produced by endogeic earthworms or another soil mesofauna. There is a reduction in the abundance of organic particles (black OM) relative to S.U. VIII, however, biogenic components are also marked by a significant increase in the number of seed coatings, charcoal, and large bone fragments (burned and unburned) as well as the presence of calcitic wood ash. A black anthropogenic combustion layer is recorded in samples from P.3. Diagenetic alteration of this unit is also evidenced by the presence of yellowish phosphatic hypocoatings (reaction rims) affecting limestone and travertine gravel, and gypsum is more abundant than S.U. VIII.

S.U. VI

Lithology type A predominates throughout this stratigraphic unit, which is characterised by poorly sorted detrital sands and gravel, dominated by tufa grains showing signs of physicochemical weathering. Phosphatic clay, phosphatic grains and guano are recorded throughout. The abundance of organic particles, gypsum infillings and biogenic components are largely similar to S.U. VII although seed coatings are notably less abundant in samples from P.3. Post-depositional bioturbation is very evident in this unit, evidenced by the presence of faecal pellets and anorthic clay nodules. A thin black lens linked to anthropogenic combustion is recorded in thin sections from P.21, with an abundance of charcoal and burned

bone. Clusters of articulated phytoliths are also recorded here. A relatively intact guano crust is recorded in the upper part of this unit from P.24.

S.U. V (lower and upper)

The transition from S.U. VI to S.U. V (lower) is marked by a notable change in the style of sedimentation (Fig. 4.4). At the macroscopic scale, this is observed in the field as a shift to much finer reddish sediments. At the microstratigraphic scale, this unit is characterised by lithology type B, being predominantly composed of diffusely bedded, moderate to well-sorted, fine calcitic sand. There is a notable reduction in the abundance of fine organic particles throughout these units. An increase in the abundance of gravel is recorded in S.U. V (upper) relative to S.U. V (lower). The fresh state of the coarse fraction points to relatively high rates of sedimentation, and the abundance of gypsum infillings is markedly increased relative to the underlying units. Anthropogenic material, such as charcoal, is relatively rare, and there is an observed decrease in the occurrence of *Celtis sp.* seed coatings. This is detected in samples from P.1, P.3 and P.21, suggesting this is not a localised effect and likely reflects a reduction in the presence of *Celtis sp.* in the vicinity of the site.

4.3.2. TOC (%) and sedimentary *n*-alkanes

The results from TOC (%) and analysis of sedimentary *n*-alkanes are presented in Figure 4.5 and Table 4.2. TOC ranged from 0.02 to 1.77%, with an average of 0.74%. The highest concentration was recorded in S.U. VIII, while the lowest concentration comes from S.U. V.

The sequence has an average total *n*-alkane concentration of 0.25 µg/g of dry sediment. Quantified samples range between 0.04 and 0.97 µg/g, with higher concentrations generally coming from the uppermost part of S.U. V. It was possible to identify *n*-alkanes in their individual chromatograms for two samples from S.U. VII but these occur at concentrations below the limit of quantification and so have been excluded. The dominance of odd over even long-chain homologues (OEP), typical of terrestrial leaf waxes, is quantified and assessed by CPI values which range from a minimum of 2.1 to a maximum of 14.1, with a mean of 5.4, indicating that lipids were not subject to significant microbial degradation. The best preservation is recorded in S.U. V (upper) (P.21).

Paq values throughout the sequence generally vary between 0–0.4, which is within the expected range for higher order terrestrial plants, except for one sample from S.U. VI which recorded a value of 0.5, indicating a mix of terrestrial and aquatic plant input at this part of the sequence. ACL values, which reflect broad changes in plant community composition, ranged between a minimum of 25.94 and a maximum of 30.10, with higher values also generally recorded through S.U. V. ACL values correspond with VPD, which has a mean value of 0.3 kPa through the full sequence. VPD reaches its maximum value (0.9 kPa) in S.U. V (upper), with a mean value of 0.5 kPa through this unit.

4.3.3. Compound specific isotope analysis (CSIA)

$\delta^{13}C_{wax}$

C₂₉ and C₃₁ *n*-alkanes were analysed for $\delta^{13}C_{wax}$ through the sequence (n=32). Reliable values (reproducibility greater than $\pm 0.5\%$) were obtained in 28 samples. We have opted to include two samples where the standard deviation between replicates was 0.6‰ for $\delta^{13}C_{wax}$ of alkane nC₂₉ when the corresponding values from the same sample for nC₃₁ were greater than $\pm 0.5\%$. Values for both C₂₉ and C₃₁ *n*-alkanes displayed a broad fluctuating trend through the sequence. For nC₂₉, $\delta^{13}C_{wax}$ ranges from -32.0‰ to -24.3‰, with a mean of -28.2‰, while nC₃₁ values fluctuate between a minimum of -32.0‰ and a maximum of -23.4‰, with a mean of -28.7‰.

δ^2H_{wax}

C₂₉ and C₃₁ *n*-alkanes were analysed for δ^2H_{wax} through the sequence (N=32), and reliable values (reproducibility greater than $\pm 5.0\%$) were obtained for ten samples. Nine of these come from S.U. V (lower and upper) and one from S.U. VIII. The remaining samples did not yield sufficient concentrations for obtaining reliable isotope values; therefore, δ^2H_{wax} values are not presented for S.U. VII or S.U. VI. For nC₂₉, δ^2H_{wax} ranges from -176‰ to -124‰. The lowest values, -176‰ and -166‰, are recorded in the uppermost part of S.U. V (P.21). For nC₃₁, δ^2H_{wax} follows a similar trend, although with more variation. Values range from -171‰ to -88‰, with the lowest values again clustered in the uppermost part of S.U. V (P.21).

4.3.4. Pollen

Of the 28 samples analysed from S.U. VIII - V (lower) (P.13), 14 were sterile and thus discarded. As a result, S.U. V (lower) is not represented in the palynological results. The remaining 14 samples (S.U. VIII - VI) yielded a total of 41 taxa (Fig. 4.6).

S.U. VIII

This unit is composed of 8 samples in total, from which the three uppermost samples (38-40, 44-47 and 51-54 cm) were found to be sterile and discarded. Arboreal elements are predominant, consistently above 66%, although with notable variability. One remarkable aspect is the internal variation of *Pinus nigra-sylvestris*, from values close to 33% (26-27 cm) to values below 8% in the subsequent sample (27-30 cm). Mesic elements, such as *Salix*, *Fraxinus*, *Corylus*, *Castanea* type, *Betula*, and *Celtis*, vary from 8.2% (26-27 cm) to 23.8% (27-30 cm). Some other Mediterranean taxa are primarily composed of *Oleae* and *Phillyrea*, with the punctual presence of Cistaceae and *Juniperus*. The total sum of these components is always below 10%, except between 26-27 cm, which is instead closer to 20%. The main non-arboreal taxon is always A. asteroideae, with values around 48% in samples from 32 to 35 cm and 18 to 20 cm, to values near 20% in the other three samples. The sample from 27 to 30 cm presents remarkable peaks of Liliaceae (31.9%) and Asteraceae cardueae (16.5%), sometimes appearing in lumps. Within the NAP, some other herbs are worth mentioning. Amaranthaceae appears between 2% (22-25 cm) and 15% (18-20 and 27-30 cm) and Poaceae ranges from 2.2% (27-30 cm) to 8.3% (32-35%). Erica is always present, varying from 1.5% (18-20 cm) to 6.5% (27-30 cm), while the presence of Artemisia is intermittent, from being absent (samples between 26 and 30 cm) to be c. 7% (the first and last sample of the unit). Cyperaceae shows values of 0.7% (27-30 cm) to 4.4% (22-25 cm).

S.U. VII

S.U. VII is composed of four samples. This unit is characterised by an abrupt decrease in arboreal pollen, which shows a progressive recovery from 45% in the lower sample to 71% in the uppermost part of the unit. The three lower samples are marked by a predominance of evergreen *Quercus* in the arboreal strata (18%, 25%, and 17%), followed by *Pinus sylvestris-nigra* (12-14%). *Cedrus* appears in low percentages c. 2% and deciduous *Quercus* shows similar values in each of the three samples (6%-8%). Other broad-leaf trees disappear in samples between 56 and 63 cm, and their values are low (below 2.2%) in samples between 66 and 73 cm. Other Mediterranean elements are scarce throughout this unit, with the sole exception of one sample between 66 and 69 cm. It presents values below 14% but the greatest variety of taxa: *Oleae*, *Phillyrea*, *Ligustrum*, *Myrtus*, and Cistaceae. The most remarkable aspect is the presence of Amaranthaceae within the non-arboreal elements, with a maximum of 45% (56-59 cm), and percentages of 21% and 31% in the other samples. Some other herbs, such as *Artemisia* (3.3% to 8.9%), Poaceae (1.2% to 8.9%), Caryophyllaceae (below 4%), and *Erica* type (1% to 5.4%) appear in low amounts. The inflexion point is constituted by the upper sample (70-73 cm), in which the AP is mainly composed of *Pinus sylvestris-nigra* (30.4%). Evergreen *Quercus* decreases (21.7%), while deciduous *Quercus* increases (11%). Other mesic trees slightly increase (*Betula*, 2%) and other Mediterranean components decrease (6%) in relation to the previous sample (12%). Within the non-arboreal pollen, Amaranthaceae decreases (9%) in favour of Asteraceae Liguliflorae type (54%).

S.U. VI

S.U. VI is composed of four samples, although one sample was found to be sterile (79-84 cm). All of the other samples in this unit exhibit arboreal pollen values above 90%. An abrupt increase of *Pinus nigra-sylvestris* (consistently above 50%) to the detriment of evergreen

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

Quercus (5%-17%) is noteworthy. *Pinus pinaster* appears, although in low percentages (3%-6%), as well as *Cedrus* (1%-3%). Deciduous taxa are present in low amounts, e.g. deciduous *Quercus* (4%-7%), *Betula*, *Castanea* type, *Corylus*, and *Salix* (all under 3%). Between 76 and 79 cm, there is a peak in some Mediterranean taxa (*Oleae* and *Phillyrea*, 9% and 8%, respectively), but they are generally scarce throughout this unit. Non-arboreal values are rather low, and their main components are Caryophyllaceae (76-79 cm, 4%), A. asteroideae (84-87 cm, 28%), and A. Liguliflorae type (89-92 cm, 33%).

S.U. V (upper)

A total of 15 samples from S.U. V (upper) were processed (4 from P.21, 5 from P.20, and 6 from P.20a). All the samples are sterile in terms of their pollen content, with the exception of one sample from P.20a. Figure 4.7 presents the palynological results of this sample expressed in percentages, together with the percentages of arboreal/non-arboreal pollen. A synthesis of the main taxa and ecological groups is presented in Figure 4.8. Arboreal pollen (50.9%) and non-arboreal pollen (49.1%) exhibit similar percentages. Evergreen *Quercus* (14.2%) is the most abundant tree, together with *Pinus nigra-sylvestris* (11.3%). Broad-leaf elements, such as deciduous *Quercus* and *Celtis*, are close to 10%, while other Mediterranean taxa, mainly represented by *Phillyrea* reach 12%. *Cedrus* and *Erica* type appear below 1% each. The most abundant herbs are Asteroideae (37.2%), Amaranthaceae (32%), and Caryophyllaceae (11.3%). It is possible to infer a patchy/semi-opened landscape alternating with open areas and mixed forests, with the punctual presence of deciduous elements. Mediterranean components are better represented than the mesic, indicating a temperate climate. The presence of xerophytic elements implies increased aridity, reinforced by the presence, albeit slight, of *Cedrus*.

4.3.5. Non-pollen palynomorphs

S.U. VIII – S.U. V (upper)

Figure 4.9 presents the general results of the non-pollen palynomorphs from S.U. VIII - V (lower) (P.13), expressed in percentages, as well as the taxonomic variability. This includes the following categories. Pteridophyta-Bryophyta: monolet and trilete spores of mosses and ferns; Algae: *Spirogyra*, *Cosmarium*, and the cyanobacteria *Gloeotrichia*; Fungi: *Glomus* sp., HdV 79, Sordariaceae, HdV 200, HdV 462, HdV 463, TM 330 C; Animalia: HdV 52, HdV 36, HdV 36c, zoo remains, coleoptera; Planta: phytoclasts and phytoclasts/panal. *Pseudoschizaeae* is of unknown origin and cannot be included in any category. *Glomus* sp. and HdV 200 are plotted against the total sum of fungi to highlight their presence within this category.

The synthetic diagram (Fig. 4.10) presents the main groups and the most representative taxa with known palaeoecological significance. These groups are divided into Pteridophyta, Bryophyta, Algae, Fungi, Animalia, and Planta, and conform with different works included in van Hove and Hendrikse (1998) and the Non-Pollen Palynomorphs Database (<http://nonpollenpalynomorphs.tsu.ru>).

A synthetic diagram with the most representative taxa and categories of palynomorphs was also plotted (Fig. 4.11). It includes the groups presented in both synthetic diagrams of pollen and NPPs. Concentrations of pollen, NPPs, and microcharcoal particles were also included. They were calculated following the volumetric method described in Loublrier (1978) and Burjachs (1990). Results are expressed in grains/gr (pollen), palynomorphs/gr (NPPs), and particles/gr (microcharcoal) of dry sediment.

4.4. Discussion

4.4.1. Site-formation at El Salt S.U VIII - S.U. V (upper)

The coarse lithological fraction observed through the El Salt sequence is largely derived from the mechanical weathering and disintegration of the local geology, particularly tufa and travertine linked to the nearby spring system and the Palaeocene limestone cliff which overlooks the site. The large limestone blocks at the base of S.U. V (lower), which seals the lower units, would once have formed the overhanging roof of a substantial rock shelter. The collapse of the roof structure corresponds with a notable change in the style of sedimentation and an abrupt decrease in evidence for human occupation. Two main phases of site formation can therefore be defined: the first phase comprises S.U. VIII - S.U. VI and predates the collapse event; and a second phase comprising S.U. V (lower and upper) which post-dates the opening up of the shelter. Differences in sediment composition and fabric between phases one and two, observable both in the field and at the microstratigraphic level, reflect the interplay of different climatic, environmental, transport, and deposition processes.

Post-depositional diagenetic alteration is reflected by the presence of gypsic features observed through soil micromorphology. This is notably more frequent in the second phase of site formation, gradually decreasing down-profile. Gypsum formation is typically linked to evaporative processes in soils under arid or semi-arid climates (Poch et al. 2018). Here, the repeated occurrence of gypsum infilling interstitial void space suggests that this is likely a secondary and sub-recent process. Decalcification of the groundmass during phase one (S.U. VIII - S.U. VI) reflects soil phosphate accumulation related to elevated input of guano. Although guano is recorded in S.U. V, it is much less abundant, and the matrix appears more calcitic.

4.4.2. Environmental and climatic context

Phase one (VIII - VI)

Soil micromorphological, palynological and our *n*-alkane evidence is consistent with other regional palaeoclimatic datasets in pointing to broad fluctuations in humidity and aridity through the course of MIS 3 (Sánchez Goñi et al. 2008; Daura et al. 2017). All samples recorded similar *n*-alkane distributions dominated by long-chain (C₂₉-C₃₁) homologues and an OEP characteristic of terrigenous higher plant input. The $\delta^{13}\text{C}_{\text{wax}}$ values across the whole range, with a mean of 28.2‰ (nC₂₉) and 28.7‰ (nC₃₁), indicate a predominant contribution from C3 plants (Diefendorf and Freimuth 2017).

The presence of guano crusts in soil micromorphology samples from S.U. VIII and S.U. VI points to recurrent intervals of stable surface exposure with relatively slow rates of sedimentation (Karkanas and Goldberg 2018). It is notable that these crusts were formed prior to the collapse of the shelter roof and similar crusts have also been recorded in other rock shelter and cave settings such as Blombos Cave (South Africa) and Liang Bua Cave (Indonesia) (Haaland et al., 2020; Morley et al., 2017). It has been suggested that the presence of guano crusts may be a good indicator of human site abandonment (Karkanas 2017). It is also interesting to note that fibrous and massive coprolites are a common component in thin sections from units deposited during phase one, although these are not as prevalent in samples reported by Leierer et al. (2019) for S.U. Xb, who describes a coprolitic matrix for that unit.

Changeable environmental conditions during phase one are reflected by variability in arboreal cover recorded in the pollen data. Internal variation in the presence of *Pinus nigra* is particularly notable in S.U. VIII and has previously been recorded in a study of scattered charcoal from this unit by Vidal-Matutano et al. (2018b). The observed

100

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

fluctuations in *Pinus nigra* may be explained by relatively short and alternating periods of higher humidity. Corresponding fluctuations in $\delta^{13}\text{C}_{\text{wax}}$ therefore likely reflect the combined effects of changes in phylogeny and humidity on $\delta^{13}\text{C}$ isotopic fractionation, which has been shown to record plant water stress in semi-arid and arid environments (Struck et al., 2020). Several major parameters drive variability of $\delta^2\text{H}_{\text{wax}}$; these include phylogeny; precipitation amount; atmospheric temperature; evapotranspiration; and precipitation source (Sachse et al., 2012; Wirth and Sessions, 2016). Like $\delta^{13}\text{C}_{\text{wax}}$, fluctuations in $\delta^2\text{H}_{\text{wax}}$ observed in the El Salt sequence reflect a response to phylogeny and water stress changes. It is known that regional $\delta^2\text{H}_{\text{precipitation}}$ values are influenced by seasonal or longer-term changes in precipitation amount, based on measurements taken at nearby GNIP stations (Connolly et al., 2019), although it is important to note that several studies have highlighted the importance of precipitation source on $\delta^2\text{H}$ values in the Iberian Peninsula, where low values are associated with an increased Atlantic precipitation origin, and higher values indicative of a Mediterranean source (Schäfer et al., 2018; Schirmacher et al., 2020; Toney et al., 2020). VPD is an absolute measure of past atmospheric moisture relative to the air saturation vapour pressure at a given temperature (Eley and Hren, 2018). It is an indicator of the extent to which the atmosphere can extract moisture from land surfaces and a robust proxy for investigating evaporative demands on vegetation. Higher VPD values correspond with periods associated with increased atmospheric demands for water. Where high VPD values correspond with high $\delta^2\text{H}$ values, it is reasonable to infer aridity as the primary control on $\delta^2\text{H}$. Where these proxies are decoupled through the sequence, we interpret this as evidence of a change in precipitation moisture source or plant phylogeny.

The main component within the arboreal pollen (AP) is evergreen *Quercus* (*Q. ilex-coccifera* type), followed by *Pinus nigra-sylvestris*. This mixed forest exhibits episodic

competitive displacements, probably related to changes in water availability, soil moisture, solar radiation levels, or fire. (Sheffer, 2012). Mediterranean elements generally appear in low percentages. This could be considered an indicator of a temperate climate at this part of the sequence. The presence of deciduous *Quercus* is low but constant, as well as some other deciduous taxa and hygrophytes, which imply some moisture. Humid conditions during phase one are also indicated by Pteridophyta and Bryophyta's presence in samples from S.U. VIII and VII. Our *n*-alkane data also recorded a *Paq* value of 0.5 in S.U. VI, which implies sedimentary input from a mix of terrestrial and aquatic plant sources. The presence of mosses or macrophytes growing in a moist environment may account for this. In S.U VIII, the presence of Spirogyra, although in low percentages, indicates a meso-eutrophic nutrient-rich environment. A reduction in fine organic particles from S.U VIII through VII corresponds with an increase in *Celtis sp.* seed coatings in the micromorphological samples and a decrease in arboreal pollen, with the three lowest pollen samples from S.U. VII presenting high values of xerophytic elements. The decrease and disappearance of hygrophytic elements and some deciduous taxa within this unit point to an opening up of the landscape at certain intervals. This is supported by the presence of *Cedrus*, although it appears in low amounts. Some pollen records show that *Cedrus* is occasionally found during abrupt deforestation events in the forest-dominated periods of the interglacials (Margari, 2002). The fact that Mediterranean elements are few may suggest increasing aridity and a decrease in regional temperatures. Although characteristic soil frost features are generally absent at the microstratigraphic level, it is worth noting that ice-segregation and related soil microstructures depend on water supply and may not develop during exceedingly dry and cold periods (Vliet-Lanoë, 2010).

Taxa associated with fire events and increased burning, mainly pyrophytic shrubs that sprout after fires, are generally present through the sequence in samples with high microcharcoal concentrations. The highest microcharcoal concentrations were identified during site formation phase one in S.U. VIII. Although the occurrence of regional fires cannot be ruled out, it is logical that the microcharcoal input here is due to anthropogenic combustion features recorded during excavation. Abundant black silt-sized particles observed in micromorphology samples from S.U. VIII, and to a lesser degree S.U. VII and VI, represent partially humified plant-derived OM but may also include small amounts of charred particles associated with combustion layers and dispersed residues recorded in S.U. VII and VI. It is notable that these features do not include an ash-rich lens overlying the charcoal-rich layer, the typical microstratigraphy for undisturbed fires recorded by Leierer et al. (2019) in S.U. Xb. This could indicate post-depositional reworking of the original fire context by wind or bioturbation; however, ash dissolution is also a likely biasing factor given the decalcification recorded in these units.

S.U. VII and S. U. VI have been dated to 49.2 ± 4.8 kya and 47.2 ± 4.4 kya, respectively. We suggest that the roof collapse blocks which seal the units of phase one correspond with GS-13 and the onset of HE 5 (c. 50 - 47 kya) (Rasmussen et al. 2014). Therefore, samples from S.U. VI, immediately before this event and composed by high percentages of arboreal pollen, likely correspond to GI-13.

Phase two (V lower - V upper)

S.U. V (lower and upper) is a polygenetic deposit characterised by a mix of windblown very fine sands and silts with coarser well-sorted fine to medium calcitic sands and micritic peloids derived from the breakdown of the Palaeocene cliff overlooking the site. These sediments are locally reworked and deposited by low-energy processes such as

103

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

surface runoff, and there is a notable reduction in the presence of tufa and travertine (lithology type B) relative to units deposited during phase one. This shift in sedimentary dynamics was undoubtedly influenced by the geomorphological restructuring of the shelter following the roof collapse, but also reflects changes in regional climatic and environmental conditions. For instance, the effects of a reduction in regional vegetation cover combined with the opening of the shelter likely account for the observed increase in windblown sediments. There is also a marked reduction at the microstratigraphic scale in the occurrence of anthropogenic materials such as charcoal or flint microflakes, mirroring the reduction in artefactual evidence noted during the excavation of these units. Sediment samples collected for pollen analysis from S.U. V (lower) were determined to be sterile, however, $\delta^{13}\text{C}_{\text{wax}}$ confirm the presence of local vegetation cover with a predominant contribution from C3 plants during the deposition of this unit.

Although chronological uncertainties make it difficult to draw robust conclusions from comparison in isotopic data between different sites, it is notable that $\delta^2\text{H}_{\text{wax}}$ values for nC₂₉ of $-135\text{‰} \pm 1$ and $-136\text{‰} \pm 4$, recorded in S.U. V (upper), are broadly consistent with $\delta^2\text{H}_{\text{wax}}$ from S.U. IVb ($-129\text{‰} \pm 4$) at the nearby site of Abric del Pastor, which has been dated to around the same time (El Salt S.U. V upper: 45 kya ± 3 ; Abric del Pastor S.U. Vb: 48 kya ± 5) (Connolly et al., 2019). Recurring oscillations observed in VPD during the deposition of S.U. V (lower) reflect fluctuations in the hydroclimatic regime. Notably, the highest VPD values are recorded in S.U. V (upper), pointing toward increased aridification. VPD correlates to ACL, which has also been found to record regional aridity under certain conditions, including in Mediterranean settings (Bush and McInerney, 2013; Norström et al., 2017). Fluctuating aridity is also indicated by the presence of *Glomus* sp, which varies in abundance throughout the sequence but reaches the highest values in S.U. V, particularly toward the top of the unit. This palynomorph is

associated with erosive processes affecting soils in dry or desiccated areas, as well as root activity (Anderson et al., 1984; van Geel et al., 1989; López-Sáez et al., 2000). It is notable that $\delta^2\text{H}_{\text{wax}}$ values are more ^2H depleted at the top of S.U. V, which we interpret as evidence of a probable change in precipitation moisture source. Taken together, our results support the chronostratigraphic model for El Salt put forward by Galván et al. (2014) which indicates that the roof collapse corresponds to HE 5, which has been widely linked to the onset of regional aridification (Müller et al., 2011; Sánchez Goñi et al., 2008). Our interpretation also chimes well with previous findings from a recent small mammal study of S.U. V (upper) which calculated an average MAP value of 13.13 mm less than present-day conditions and point to a transition from a woodland dominated environment to more open and arid conditions (Fagoaga et al., 2019). Evidence for similar shifts in regional conditions to more open and arid landscapes coincident with Neanderthal disappearance have also recently been reported in Central Iberia and the Cantabrian region (Wolf et al., 2018; Jones et al., 2018).

4.5. Concluding remarks

In order to investigate the palaeoclimatic context for the final Neanderthal occupations at the Middle Palaeolithic site of El Salt, the sedimentary sequence has been analysed using soil micromorphology, lipid biomarker *n*-alkane abundances (CPI, ACL, VPD, LAR, Paq), compound-specific hydrogen and carbon isotopic records from fossil leaf waxes ($\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$), bulk organic geochemistry (TOC), pollen, and non-pollen palynomorphs. Our multiproxy palaeoenvironmental study of S.U. VIII – S.U. V (upper) has allowed us to draw the following conclusions:

- Two distinct phases of site formation can be distinguished. Phase one, which comprises S.U. VIII – S.U. VI, precedes the collapse of the rock shelter roof and is characterised at the microstratigraphic scale by lithological coarse fraction

dominated by tufa and travertine related to the nearby relict Upper Pleistocene freshwater spring system. The palaeoenvironmental setting during this phase is characterised by mixed forest vegetation and episodic fluctuations in humidity and periods of extended soil surface exposure. Deposits laid down during this phase of site formation yield abundant evidence for Neanderthal occupation activities, including hearth construction and flint knapping.

- Phase two, which comprises S.U. V (lower) – S.U. V (upper), immediately follows the collapse of the shelter roof. A distinct change in sedimentation style characterises this phase with a strong component of wind-blown sediments, a marked reduction in fine organic particles, the occurrence of tufa and travertine, and anthropogenic components. Our palaeoenvironmental data points to a scenario of increasing aridity at this time, between HE 5 and HE 4.
- This study contributes to a better understanding of the diachronous and regional nature of Neanderthal disappearance from the Iberian Peninsula and adds new lines of evidence for exploring the role of climate and environmental change in driving Neanderthal demographic collapse.

Abstract

This paper reports on a series of heating experiments that focus on *n*-alkanes extracted from leaf, bark, and xylem tissues of the *Celtis australis* plant. These lipid biomarkers were analysed for their compound-specific hydrogen isotopic composition ($\delta^2\text{H}_{\text{wax}}$) under limited oxygen conditions at 150 °C, 250 °C, 350 °C and 450 °C. Our results reveal isotopic variations in wax lipids of different plant organs during short-term low-temperature combustion. We conclude that, in the absence of a detailed characterisation of the depositional environment in advance of sampling, $\delta^2\text{H}_{\text{wax}}$ values in archaeological or otherwise highly anthropogenic environments should be interpreted cautiously. In addition, we observed that variation in $\delta^2\text{H}_{\text{wax}}$ of leaves is minimal at temperatures ≤ 350 °C, highlighting the potential for $\delta^2\text{H}_{\text{wax}}$ in thermally altered combustion substrates to yield palaeoclimate information, which could allow researchers to investigate links between archaeological and climatic records at a high spatial and temporal resolution.

5.1. Introduction

5.1.1. Hydrogen isotope composition of plant waxes

Lipid biomarkers are organic molecules which can be traced to a specific biological source (Cranwell et al., 1987; Eglinton and Hamilton, 1967; Evershed, 1993; Evershed et al., 1999; Ficken et al., 2000). Compound-specific hydrogen isotope analysis of *n*-alkanes ($\delta^2\text{H}_{\text{wax}}$) derived from terrestrial and aquatic plant waxes has been shown to record plant source water's isotopic composition, most commonly precipitation (Sachse et al., 2012). The hydrogen isotopic composition of sedimentary *n*-alkanes has thus emerged as a robust proxy for palaeohydrological reconstruction and in the last decade has been increasingly employed in archaeological settings (Brittingham et al., 2019; Diefendorf et al., 2010; Diefendorf and Freimuth, 2017; Glauber et al., 2020; Jordan et al., 2017; Magill et al., 2016). Numerous studies have reported on the wide range of environmental factors which govern hydrogen isotopic fractionation in plant waxes, which include precipitation $\delta^2\text{H}$, precipitation amount, plant type, plant physiology, temperature, aridity, seasonality, and humidity (Gamarra et al., 2016; Liu and An, 2018; Niedermeyer et al., 2016; Sachse et al., 2012). However, it is notable that despite the recent upsurge in the application of this proxy in archaeological settings, little attention has been afforded to the potential impacts of human activities on $\delta^2\text{H}_{\text{wax}}$. Anthropogenic combustion features and their associated residues, which are chronologically and geographically ubiquitous in archaeological contexts, particularly stand out as an important source of potential bias and the effects of short-term low temperature (< 450 °C) combustion on $\delta^2\text{H}_{\text{wax}}$ values are not well understood.

5.1.2. Anthropogenic combustion features

Anthropogenic combustion features, or hearths, have been the focus of a considerable body of archaeological research in recent years using an array of high-resolution analytical techniques (Butler et al., 2019; Fernández Peris et al., 2012; Haaland et al., 2017; Henry, 2012; Mallol and Henry, 2017; Urban et al., 2019; Whitau et al., 2018). The processes involved in forming anthropogenic combustion features are complex and subject to a considerable range of culturally and environmentally mediated variables. However, at the most basic level, these features are composed of a thermally altered substrate overlain by a black combustion layer resulting from the deliberate exploitation and management of fire by one or more humans in the past. Experimental studies suggest that the occupation surface or substrate on which the fire is lit do not typically exceed temperatures of 300 °C and may provide preferential conditions for the preservation of lipid biomarkers (Mallol et al., 2013; March et al., 2014). The most rudimentary form of anthropogenic combustion feature is a *simple hearth* in which combustion is carried out on a horizontal surface. Other common forms include *cuvette* fires, or *pit hearths*, in which the combustion is carried out in a bowl-like depression. In some instances, pebbles or flagstones may be placed around the fire in a horizontal or vertical position and act as heat retainers, altering the combustion's archaeological and sedimentary signature (Aldeias, 2017; Leierer et al., 2020; March et al., 2014).

Traditionally, palaeoenvironmental information from combustion features has been derived from analyses of the associated charcoal assemblages (e.g. Braadbaart and Poole, 2008; Vidal-Matutano, 2018a; Vidal-Matutano et al., 2015; Whitau et al., 2018) or phytoliths (e.g. Albert and Cabanes, 2007; Allué et al., 2012; Toffolo et al., 2019; Wroth et al., 2019), both of which are the product of human activities related to fire. The application of lipid biomarker analyses, despite being first approached as early as the

1980s (Cliquet et al., 1989; March et al., 1989; Rottlander 1989, 1990), is still, however, not widely employed for the study of combustion features. In recent years, decreasing costs and improved access to instrumental analyses has led to a modest increase in the number of studies that have sought to exploit lipid biomarkers' potential and their associated compound-specific isotope ratios to investigate both experimentally derived and archaeological datasets. To date, however, most of these studies have focused on questions related to cooking activities and the identification of potential fuel sources (Buonasera et al., 2019; Choy et al., 2016; Crass et al., 2011; Jambrina-Enríquez et al., 2019; Kedrowski et al., 2009; Lejay et al., 2016; March, 2013).

Here, we conducted a series of heating experiments to evaluate molecular and isotopic changes to plant-derived wax lipids during short duration combustion events under limited oxygen conditions using leaves, bark and xylem tissues of *Celtis australis*. These plant organs represent common fuel sources in archaeological settings and are likely to be an important source of organic residues in archaeological combustion features. In addition, fine charred particles produced during the combustion of these fuel sources are likely to be locally dispersed in surrounding sediments and may impact isotopic values, leading to incorrect palaeoenvironmental reconstructions. We aimed to assess the degree of preservation of climatic signals in $\delta^2\text{H}_{\text{wax}}$ in anthropogenic combustion features and account for potential biases that could arise due to the mixing of microscopic fine charred particles in the surrounding sediments.

5.2. Materials and methods

5.2.1. Sample collection, preparation, and combustion

Leaf and branch samples of *Celtis australis* were collected in July 2015 and April 2016 from the area surrounding the Middle Palaeolithic site of El Salt in Alcoy, Spain (726 m

110

asl). All samples were rinsed with distilled water to remove potential contaminants and oven-dried at 60 °C for 24 h at the Archaeological Micromorphology and Biomarker Laboratory (AMBI), Universidad de La Laguna, Tenerife.

Leaf (4 g; 1 cm length) and branch (20 g; 2 cm diameter) samples were placed in ceramic crucibles (4.2 cm x 2.5 cm) and covered with Al foil to limit the supply of O₂ during the heating process. All samples were heated in a muffle furnace with a ramp rate of 26 °C/min for a duration of 1 h to temperatures of 150 °C; 250 °C; 350 °C; 450 °C. Following this, samples remained in the closed furnace to cool overnight before being homogenised into a fine powder using a pestle and mortar.

5.2.2. Lipid extraction, analysis, and quantification

All non-volumetric materials were calcined at 450 °C for a duration of 10 h to eliminate potential contaminants. Lipids extraction was carried out with dichloromethane/methanol (DCM:MeOH, 9:1) (10–20 mL) by ultrasonic extraction (3 × 30 min) at controlled temperatures < 30 °C. Samples were subsequently centrifuged (3 × 10 min at 4700 rpm) and filtered through annealed glass wool. Solid-phase column chromatography (2 mL column with glass wool, 0.1 g quartz sand (50–70 mesh) and 1 g of activated silica (70–230 mesh) was used to separate the lipid extract into fractions of differing polarity. Alkanes were eluted with $\frac{3}{8}$ dead volume (DV) *n*-hexane (DV 1.5 mL, $\frac{3}{8}$ DV 562 μ L). Samples were subsequently dried under a steady stream of N₂ in an Organomation evaporator, internal standard (IS) 5 α -androstane (2000 mg/L in DCM, purity \geq 99.9%, Sigma-Aldrich) 8 mg/L was then added. The compounds were analysed by gas chromatography (GC) with a coupled mass-selective detector (GC-Agilent 7890B, MSD Agilent 5977A) which was equipped with a HP-5MS capillary column ((5%-phenyl)-methylpolysiloxane, length: 30m, ID: 250 μ m, film thickness 0.25 μ m). A temperature

program with an initial temperature of 70 °C for 2 min and a heating rate of 12 °C/min to 140 °C and a final temperature of 320 °C was applied with a heating rate of 3 °C/min for 3 min and a total run time of 82.83 min, using a Helium carrier gas (2mL/min). The multimode injector was held at a split ratio of 5:1 at an initial temperature of 70 °C for 0.85 min and heated to 300 °C at a programmed rate of 720 °C/min.

Identification of individual compounds was carried out by comparing retention times and mass spectra to those of reference compounds (mix C₈-C₄₀ and 5 α -androstane, Supelco) and mass spectral library databases (NIST). Quantification of concentrations was achieved using calibration curves that plot the ratio Area/Area_{IS} versus the reference compounds' concentration. Correlation coefficients for each sample were higher than 0.995. Concentration is expressed here in terms of μg of individual compound per gram of dry sample ($\mu\text{g gds}^{-1}$).

5.2.3. Compound-specific hydrogen isotope analysis

Compound-specific hydrogen isotope analysis was performed using a Thermo Scientific Isotope Ratio Mass Spectrometer (IRMS) Delta V Advantage. The IRMS was coupled to a GC Trace1310 through a Conflo IV interface with a temperature converter GC Isolink II, with a Trace Gold 5-MS (Thermo Scientific) fused silica capillary column ((5%-diphenyl)-dimethylpolysiloxane, 30 m length x 0.25 mm i.d., 0.25 μm film thickness). A helium flow rate of 1.5 mL/min was employed for all measurements carried out in triplicate. Data acquisition and processing were carried out using Isodat 3.0 software (Thermo Scientific). Hydrogen ($\delta^2\text{H}$) isotope values are reported for *n*-alkanes C₂₉ and C₃₁. Samples were injected using a Programmed Temperature Vaporising injector (PTV) in splitless mode. Temperatures initially increased from 60 °C to 79 °C (held 30 s, rate 10 °C/min) and then to 325 °C (held 3 min, rate 10 °C/s) and finally to 350 °C (held 3

min, rate 14 °C/s). For the GC oven, a 2 min isothermal period at 70 °C increasing to 140 °C (held 2 min, rate 12 °C/min) was followed by an increase to 320 °C (held 15 min, rate 3 °C/min). The high-temperature conversion (HTC) oven was maintained at 1420 °C for all samples. Values were normalised to the Vienna Standard Mean Ocean Water (VSMOW) scale using an *n*-alkane Schimmelmann type A6 mixture (*n*-C₁₆ to *n*-C₃₁) of known isotopic composition (Arndt Schimmelmann; Biogeochemical Laboratories, Indiana University). Reproducibility greater than ± 5.0‰ was attained for most samples, where reproducibility was less than ± 5.0‰, this is clearly stated.

5.3. Results and discussion

5.3.1. Concentration and molecular ratios of *n*-alkanes

Fossil leaf waxes ranging from *n*C₁₈ – *n*C₃₃ were detected in the leaf samples, and from *n*C₁₆ – *n*C₃₁ in the bark samples and xylem samples. Total *n*-alkane concentration (µg/g dried sample), Carbon Preference Index (CPI₂₅₋₃₃) (Bray and Evans, 1961), and Average Chain Length (ACL₂₅₋₃₃) (Freeman and Pancost, 2013) have previously been reported in Jambriña-Enriquez et al. (2018) and are outlined for comparison in Table 5.1 below.

Table 5. 2 Hydrogen isotope values of individual long-chain n-alkanes in thermally unaltered reference samples and heated samples of *Celtis australis* leaf, branch interior (xylem) and exterior (bark). The $\delta^2\text{H}_{\text{wax}}$ values are normalised to the Vienna Standard Mean Ocean Water (VSMOW) standard. Values are expressed in per mil (‰) with one standard deviation. * denotes samples where reproducibility was less than $\pm 5.0\text{‰}$ following three replicates.

5.3.2. Variation in $\delta^2\text{H}_{\text{wax}}$ of thermally unaltered reference samples and heated samples of *Celtis australis*

Here we measured the hydrogen isotope composition of different plant organs of *Celtis australis* during short-term combustions (1 h) at temperatures of 150 °C, 250 °C, 350 °C

and 450 °C under limited oxygen conditions (Fig. 5.1-3). We report only the $\delta^2\text{H}_{\text{wax}}$ of nC_{27} , nC_{29} and nC_{31} because these long-chain homologues were recovered in sufficient concentrations for isotopic determination and because these are the most common homologues employed for palaeoecological reconstruction. This data is presented in Table 5.2.

The maximum variation in hydrogen isotope composition observed for each of the sample sets was $\sim 49\%$ (nC_{27}), $\sim 80\%$ (nC_{31}), and $\sim 94\%$ (nC_{31}) for leaves, xylem, and bark, respectively. Based on the nC_{31} homologue, for which isotopic determinations could be made using unaltered reference samples in all three sample sets, leaves are enriched in ^2H (-128.2%) by $\sim 65\%$ relative to xylem (-193.4%) and $\sim 23\%$ relative to bark (-151.4%). This variation can be explained by physiological and chemical differences which affect alkane biosynthesis and isotopic fractionation in different plant tissues (Post-Beittenmiller, 1996). Although it has been demonstrated that isotopic fractionation of plant xylem water does not occur during root uptake and transport to the leaf, thereby ensuring xylem carries the isotopic signature of the source water, significant differences in $\delta^2\text{H}$ values have been reported between xylem sap, twigs, roots and wood core (Zhao et al., 2016). Sanchez-Bragado et al. (2019) have also demonstrated that hydrogen isotopic fractionation is affected by photosynthetic processes, with significant differences in $\delta^2\text{H}$ values observed between plant photosynthetic organs and heterotrophic organs. $\delta^2\text{H}$ values were beyond the detection limit in unaltered xylem samples for nC_{27} and nC_{29} and corresponding samples heated to temperatures > 350 °C for those homologues. For nC_{29} and nC_{31} , the most common homologues targeted for terrestrial palaeoenvironmental reconstruction, $\delta^2\text{H}$ values in leaves was generally minimal at temperatures up to 350 °C, with a maximum variation of $\sim 4\%$ and $\sim 7\%$ respectively, ranging from -131% to -135% and -128% to -135% . This is followed by an increasing trend in ^2H values at 450 °C. In

Firmado por: Rory Connolly . UNIVERSIDAD DE LA LAGUNA	Fecha: 17/02/2021 14:01:27
Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

xylem samples, there is a decreasing trend toward ^2H depleted values between 150 °C and 250 °C of $\sim 19\text{‰}$ ($n\text{C}_{27}$) and $\sim 35\text{‰}$ ($n\text{C}_{29}$) despite an increase in total *n*-alkane concentration in these samples. Although reliable $\delta^2\text{H}$ values were not obtained for the unaltered xylem samples for $n\text{C}_{27}$ and $n\text{C}_{29}$, making it difficult to meaningfully compare that sample set, a general decreasing trend is observed for $n\text{C}_{31}$ between the reference samples and those heated to 250°C. It is also notable that bark samples followed a similar trend to leaves with more depleted values at 250 °C, followed by a slight increase in $\delta^2\text{H}$ values at 350 °C. Total variation in hydrogen isotope composition of the heated bark samples was in the range of $\sim 57\text{‰}$ ($n\text{C}_{27}$), $\sim 79\text{‰}$ ($n\text{C}_{29}$), and $\sim 94\text{‰}$ ($n\text{C}_{31}$).

To summarise, $\delta^2\text{H}$ values in *n*-alkanes from leaf waxes were unaltered up to 350 °C with an increasing trend toward ^2H enriched values occurring at 450°C. In contrast, in wood tissues (bark and xylem) the original unaltered $\delta^2\text{H}$ signal was lost at 250 – 350 °C. The observed variations are similar to those described by Jambrina-Enríquez et al. (2018).

5.3.3. Implications for the application of compound-specific hydrogen isotope analysis of fossil leaf waxes in archaeological settings

It is widely accepted that long-chain *n*-alkanes ($n\text{C}_{27}$ - $n\text{C}_{33}$), derived from epicuticular leaf waxes, represent the dominant source of *n*-alkanes in sediments (Eglinton and Hamilton, 1967). However, in archaeological contexts or other anthropogenic settings we should not discount the possibility that other plant organs may represent a source of sedimentary *n*-alkanes. Well preserved charred plant tissues and fragments of microcharcoal, which are not visible at the macroscopic scale of excavation, are frequently observed in soil micromorphological samples collected from archaeological sites (Friesem et al., 2014; Goldberg et al., 2009; Leierer et al., 2019; Mallol et al., 2013). In occupation horizons, these materials may represent fuel residues directly linked to combustion features, or

Firmado por: Rory Connolly . UNIVERSIDAD DE LA LAGUNA	Fecha: 17/02/2021 14:01:27
Carolina Mallol Duque UNIVERSIDAD DE LA LAGUNA	17/02/2021 14:58:12
María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

alternatively, they may have been deposited through natural agents. For instance, microcharcoal is commonly registered in palynological datasets and has been utilised to study the frequency of natural fires linked to climate shifts (Clark, 1988; Swain, 1973; Val-Peón et al., 2019). Our findings emphasise the need to carefully consider the depositional setting, particularly relating to anthropogenic combustion activities, when interpreting molecular or isotopic information from sedimentary *n*-alkanes in archaeological contexts. The unintentional incorporation of fine charred particles within sediment samples, which has been subjected to temperatures of 450 °C or greater, could lead to misinterpretations of leaf wax $\delta^2\text{H}$ values and molecular ratios such as CPI and ACL, with significant implications for palaeoclimatic reconstruction. The application of complementary techniques, such as soil micromorphology, can identify charred particles' presence and help eliminate potential biases in the molecular and geochemical datasets. This approach has already effectively been demonstrated at the Middle Palaeolithic site of Abric del Pastor (Alcoy, Spain) (Chapter 4), where abrupt fluctuations in *n*-alkane distribution and compound-specific carbon and hydrogen isotope values through stratigraphic units IVd and IVc were interpreted as resulting from the presence of microscopic charred fuel residues in the lipid biomarker sediment samples (Connolly et al., 2019).

On the other hand, our results here demonstrate that the change in $\delta^2\text{H}$ values in leaves was generally minimal at temperatures up to 350 °C, with a maximum difference of ~4‰ and ~7‰ for nC_{29} and nC_{31} respectively, ranging from -131‰ to -135‰ and -128‰ to -135‰. This relatively minor ^2H depletion is despite a dramatic decrease (~79%) in total *n*-alkane concentration within this temperature range, from 459.1 $\mu\text{g/g}$ to 97 $\mu\text{g/g}$. Although the effects of short-term low-temperature combustion on *n*-alkane $\delta^2\text{H}$ values have not been widely investigated, our results are broadly consistent with Wang et al.

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

(2017), who observed a maximum difference of ~10‰ in $\delta^2\text{H}$ values of a pure *n*-alkane mixture ($n\text{C}_{15}$ to $n\text{-C}_{38}$) heated at 100–300 °C. However, it is worth noting that their study was based on a heating duration of 24 h under oxygen-free conditions. As these do not reflect real conditions in the archaeological record, and anthropogenic combustion processes are not produced in the total absence of oxygen, there is a need for more studies like ours which seek to replicate field conditions in so far as is possible in controlled laboratory settings.

The result from our *Celtis australis* leaf samples is potentially significant, as it implies that low-temperature alteration of fossil leaf waxes within sediments (<350 °C) may not eradicate the hydrogen isotope climate signature, opening the door to high-precision onsite palaeoclimate records from lipid biomarkers recovered from archaeological combustion features. In their microstratigraphic study, Mallol et al. (2013) have drawn attention to the potential for thermally altered sedimentary substrates, which underly the black layer of flat combustion features, to yield archaeological information about human activity preceding the combustion event. These sediments, which represent occupation surfaces on which fires were built, do not typically exceed temperatures of 350 °C and may therefore be suitable for compound-specific hydrogen isotope analysis. Such an approach would allow for well-dated palaeoclimate records directly associated with human activities and create a new avenue for exploring human responses to climate change at the site-specific scale. A similar approach has recently been developed by Roffet-Salque et al. (2018) who demonstrated that $\delta^2\text{H}$ values of lipid residues preserved in pottery from Late Neolithic levels at Çatalhöyük carried the climatic signature of the North Atlantic abrupt climate event which occurred 8.2 kya.

Notwithstanding the relatively small number of samples analysed here, our results provide the initial steps toward establishing boundary conditions for constraining the

maximum potential alteration of fossil leaf waxes in thermally altered sediments. Our results are well complemented by Jambrina-Enríquez et al. (2018), who demonstrated that the $\delta^{13}\text{C}_{\text{alkane}}$ signature of *Celtis australis* leaves also remains constant up to 350 °C under limited oxygen conditions, which suggests that the thermally altered combustion substrates could be targeted for both hydrogen and carbon isotope analysis of individual *n*-alkanes. These isotope signatures respond to different environmental controls and when deployed in tandem allow for more robust conclusions than single isotopic analysis (Bi et al., 2005; Collins et al., 2017; Wu et al., 2018).

5.4. Concluding remarks

Here we investigated the hydrogen isotope composition of thermally unaltered and charred *Celtis australis* leaves, xylem, and bark during short-term combustions (1 h) under limited oxygen conditions in a laboratory-controlled setting, at temperatures up to 450 °C. Our results demonstrate that although significant variation in $\delta^2\text{H}_{\text{wax}}$ is observed in the xylem and bark samples, changes in $\delta^2\text{H}_{\text{wax}}$ of leaf samples are generally minimal up to 350 °C, however, at temperatures exceeding this, considerable changes in hydrogen isotopic composition occur. Our results sound a cautionary note on the application of $\delta^2\text{H}_{\text{wax}}$ as a palaeoclimate proxy in archaeological contexts where the depositional environment is not well understood. We propose that this proxy be enhanced by a detailed characterisation of soil microstratigraphy, which can help eliminate potential isotopic biases that arise due to the mixing of charred microscopic particles (≥ 450 °C) in sediment samples. Nevertheless, our observations highlight the potential for $\delta^2\text{H}_{\text{wax}}$ to record and retain palaeoclimate information at temperatures ≤ 350 °C and could be employed to target thermally altered archaeological combustion substrates and link climatic and archaeological datasets at a high spatial and temporal resolution.

Chapter 6: General discussion and conclusion

6.1. Discussion

In this thesis, open questions regarding the application of microscopic and molecular methods for providing new sources of information to approach the relationship between past peoples and their environments have been addressed, with particular reference to the role of climate in Neanderthal social and cultural evolution in Eastern Iberia. Previous studies have demonstrated the potential of archaeological soil micromorphology (Aldeias and Bicho, 2016; Goldberg et al., 2009; Haaland et al., 2020; Mallol, 2006; Stahlschmidt et al., 2018) and compound-specific isotope analysis (Brittingham et al., 2019; Carr et al., 2014; Collins et al., 2017, 2013; Diefendorf et al., 2008; Wang et al., 2016) to yield high-resolution site formation and palaeoenvironmental information across multiple spatial and temporal scales, however, no study has previously deployed these techniques systematically and in tandem for palaeoenvironmental reconstruction in an archaeological setting, nor sought to integrate these approaches with traditional palaeoenvironmental proxies for archaeological research.

The preceding chapters have demonstrated that the combined use of archaeological soil micromorphology and compound-specific carbon and hydrogen isotope analysis of sedimentary fossil leaf waxes can provide additional and complementary information for investigating the relationships between past peoples and their environment. In the third chapter of this thesis, we applied these techniques to investigate climatic variability through Abric del Pastor's sedimentary sequence. This Middle Palaeolithic rock shelter has previously been dated between 43 kya and 72 kya, a key chronological interval for understanding the potential detrimental role of deteriorating MIS 4 global climate conditions on regional Neanderthal populations. Our combined microscopic and

molecular approach was complemented by supplementary palaeoenvironmental data from other proxy sources, which included anthracology, micro-vertebrate, and macro-faunal analyses, offering an opportunity to explore the complementarity of our novel approach with more traditional archaeological datasets, one of the key objectives (iii) set out in chapter 1. The results of this study showed that, at the microstratigraphic scale, evidence for cold climate conditions were present in the form of characteristic cryoturbation features, which included platy and granular soil microstructures, soil cappings, and fissured clasts typical of soils and sediments affected by cyclical freeze-thaw processes (Vliet-Lanoë et al., 2004; Vliet-Lanoë, 2010). We also observed micromorphological evidence for localised variation in sedimentary rates, where redoximorphic features and dissolution of the calcitic matrix was interpreted as evidence of more prolonged surface exposures. These processes were particularly notable in S.U. IVd and was key for interpreting trends in the lipid molecular data at that part of the sequence.

Our results confirmed that compound-specific carbon and hydrogen isotope values of *n*-alkanes recovered from Pleistocene sediments at Abric del Pastor record a local vegetation and regional climate signal with high fidelity, and we interpret co-varying $\delta^2\text{H}_{\text{wax}}$ and $\delta^{13}\text{C}_{\text{wax}}$ values as primarily responding to the combined effects of changes in regional moisture source (i.e. Mediterranean versus Atlantic), precipitation amount and fluctuations in temperature and evaporative stress. With the available evidence, it is not possible to meaningfully disentangle these processes, however, our interpretation is broadly in line with other regional studies in the Iberian Peninsula (Jambrina-Enríquez et al., 2017; Muñoz-Díaz and Rodrigo, 2004; Schirmacher et al., 2020; Toney et al., 2020). Co-varying trends in the molecular ratios CPI and ACL in S.U. IVc and IVd were interpreted as the result of contamination due to fine charred particles from anthropogenic

combustion features being locally dispersed in sediments sampled for lipid biomarkers. The accumulation of these fine particles was undoubtedly accentuated by the slowdown in sedimentary rates observed at the microstratigraphic scale. These observations urge a significant degree of caution in interpreting the lipid molecular and geochemical data at this part of the sequence and motivated the experimental study described in chapter 5. Supplementary palaeoenvironmental data obtained from anthracological, micro-vertebrate and macro-faunal analyses allowed us to 'plug the gap' left by the lipid molecular data in S.U. IVc and IVd, which demonstrates the clear advantage of investigating multiple lines of evidence in parallel. These indicated dry to semi-arid supramediterranean conditions where open dry woodland formations characterise the upper parts of the Barranc del Cinc. Within the ravine where the site is located, Mediterranean mixed forest taxa and riverine species were present in sufficient abundance to provide vital resources for local Neanderthal groups in the form of woody fuel and a habitat for species such as *Testudo hermanni*, which were an important subsistence source. Notwithstanding archaeological evidence from across Europe through MIS 4 which indicates that climatic cooling had detrimental effects on Neanderthal populations, leading to population shrinkage or redistribution (van Andel and Davies, 2003), our results from Abric del Pastor suggest that a mosaic of biotopes likely characterised local conditions along the Central Mediterranean coast of Eastern Iberia. Even across short distances, local variation in conditions was likely influenced significantly by local topographic factors. We have provided evidence for continued Neanderthal occupation at Abric del Pastor despite fluctuations in regional climate conditions. We propose that c. 63 kya \pm 5 the Barranc del Cinc acted as a vegetation refugium which may have been crucial for the survival of regional Neanderthal populations. Our results highlight the potential for regional and local environmental

variability to be masked within large global climatic datasets and call attention to the need for more onsite climate records directly correlated with archaeological data.

In the fourth chapter of this thesis, we provide new insights into site formation and palaeoenvironmental conditions during the deposition of stratigraphic units VIII – V (upper) from the Middle Palaeolithic site of El Salt, which help establish the palaeoclimatic context for the final Neanderthal occupations recorded in the Alcoy region of Eastern Iberia c. 45 kya during MIS 3. Here we combined our novel microscopic and molecular approach with palaeoenvironmental data derived from a detailed study of pollen and non-pollen palynomorphs. We identified two distinct phases of site formation: phase one comprised stratigraphic units VIII – VI and precede the collapse of the rock shelter roof; phase two is represented by stratigraphic unit V (lower and upper). The depositional units of phase one were characterised at the microstratigraphic scale by lithological coarse fraction dominated by tufa and travertine related to the nearby relict Upper Pleistocene freshwater spring system. The presence of guano crusts in our soil thin sections indicates intermittent periods of surface stabilisation of unknown duration, which may correspond with the establishment of vegetation and broad fluctuations in regional environmental conditions. Our pollen data revealed local vegetation dominated by mixed forest taxa which underwent episodic competitive displacements, likely linked to water availability changes.

Our lipid data from phase one shows that *n*-alkanes were not subject to significant microbial degradation. Although $\delta^{13}\text{C}_{\text{wax}}$ and $\delta^2\text{H}_{\text{wax}}$ results from this phase are too few to draw wholesale conclusions from the isotope data, the general "saw-toothed" pattern observed in total alkane concentration, as well as in VPD, reflect the same changes in vegetation and moisture indicated by the other proxies. The high frequency of anthropogenic materials such as charcoal, burned bones, and flint microflakes in our thin

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

section samples from units VIII – VI, in addition to evidence recovered during excavation, suggest that Neanderthal occupations during phase one at El Salt were recurrent irrespective of persistent environmental oscillations. We propose that S.U. VI (47.2 ± 4.4 ka BP) corresponds with GS-13, just before the onset of HE 5. The collapse of the rock shelter roof marked the beginning of site formation phase two through stratigraphic unit V (lower and upper) and the large limestone blocks from this event seal the underlying units deposited during phase one. Our data supports the argument put forward by Galván et al. (2014) who suggest that the shelter's destabilisation and the roof collapse event correspond to changes in regional environmental conditions provoked by HE 5. Our microstratigraphic study confirms that phase two is characterised by further complexification of the local depositional mechanisms, with a mix of windblown very fine sand and silt with coarser (fine and medium sand) sediments derived from the breakdown of the Palaeocene cliff overlooking the site, all of it locally and syndepositionally reworked and deposited by low-energy processes (runoff). A reduction in regional vegetation cover may account for this increase in windblown sand and silt. A significant reduction in the presence of tufa and travertine in the coarse fraction of soil thin sections representing phase two reflects this shift in transport and deposition processes due to the restructuring of the rock shelter and a likely increase in the sedimentation rates. Soil samples collected for pollen analysis from S.U. V (lower) were found to be sterile, however, despite this, $\delta^{13}C_{wax}$ values at this part of the sequence confirm the presence of a C3 vegetation signal. VPD values fluctuate through S.U. V (lower) and are generally higher in S.U. V (upper), indicating a high evaporative demand of ambient air and a trend toward more arid regional environmental conditions, consistent with the presence of the *Glomus* sp palynomorph, which is common in dry or desiccated areas soils and reached the highest values in S.U. V. Our finding also supports the results

presented in Fagoaga et al. (2019), which point to arid conditions during the deposition of S.U. V (upper) based on analysis of the micro-vertebrate assemblage. Regional aridification and climatic deterioration in the area around Alcoy would undoubtedly have affected the availability of critical resources that Neanderthal groups depended on for their survival. The results of our study add new detail and help frame the abrupt decrease in evidence for Neanderthal occupation during phase two at El Salt, adding weight to the argument that the breakdown of regional Neanderthal populations in Eastern Iberia occurred around the time of HE 5 and before the onset HE 4 (Galván et al., 2014). A similar scenario is described by Wolf et al. (2018) who observe that loess deposition and regional aridification in the Upper Tagus Basin occurred between HE 5 and HE 4, coinciding with the disappearance of Neanderthal populations in Central Iberia.

In the fifth chapter of this thesis, our experimental study addresses a significant research gap by exploring potential biases which could arise when using $\delta^2\text{H}_{\text{wax}}$ as a climatic proxy in archaeological contexts affected by anthropogenic combustion activities. Although much has been published on the range of environmental and physiological factors affecting ^2H fractionation in plants (Kahmen et al., 2011; Liu and An, 2018; Sachse et al., 2009, 2006; Schwab et al., 2015), the potential impact of human activities on $\delta^2\text{H}_{\text{wax}}$ has largely been overlooked in previous studies since the development and application of this proxy have mostly focused on sediments which are presumed to be unaffected by human activities. It is critically important that this gap in our knowledge is addressed, particularly as $\delta^2\text{H}_{\text{wax}}$ increasingly comes to be applied in archaeological contexts where combustion activities are ubiquitous and the mixing of fine charred particles in sediments is commonplace. This study revealed that variation in $\delta^2\text{H}_{\text{wax}}$ with increasing temperature differs between plant organs and tissue types, with a high variation corresponding to low alkane concentrations in bark and xylem samples. Significantly, changes in $\delta^2\text{H}_{\text{wax}}$ of leaf,

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

which is the predominant source of *n*-alkanes in sediments, showed a high degree of variation at temperatures ≥ 450 °C. This result highlights the importance of first characterising the depositional environment before sampling sediments for $\delta^2\text{H}_{\text{wax}}$. It is proposed here that soil micromorphology represents the most robust and comprehensive technique for identifying fine charred particles in archaeological deposits and could be used to help eliminate potential sources of bias in $\delta^2\text{H}_{\text{wax}}$ and lead to more secure palaeoenvironmental interpretations.

Another significant observation from the fifth chapter results was that variation in $\delta^2\text{H}_{\text{wax}}$ from leaf samples at temperatures ≤ 350 °C was generally small. Although further analyses are required to investigate whether this result is repeated across different plant species, it suggests that $\delta^2\text{H}_{\text{wax}}$ could theoretically be utilised to target thermally altered archaeological combustion substrates, providing a new source temporally and spatially resolved onsite climate data that can be directly linked to archaeological datasets. Considering recent advances in high-precision radiocarbon dating, including ongoing developments and improvements in the application of Bayesian statistical analyses (Bayliss, 2015; Carleton, 2021; Pettitt and Zilhão, 2015), the potential to yield molecular climate data directly from anthropogenic combustion features is significant. This approach could offer a powerful means to construct new well-dated onsite paleoclimate records against which longstanding deterministic models of human responses to climatic change can be tested. These methods would also be well complemented by the analysis of $\delta^2\text{H}$ values of lipid biomarkers preserved on other archaeological materials, which has recently been investigated by Roffet-Salque et al. (2018). These advances are especially pertinent for understanding significant biogeographic, cultural, and evolutionary changes of the Pleistocene, such as the demise of Neanderthal populations at the MUPT, where

long-term continuous palaeoenvironmental sequences are mostly absent or far removed from the relevant archaeological assemblages.

6.2. Hypotheses

The hypotheses defined in Section 1.7 are tested against the evidence presented from the studies outlined in this thesis. The null hypothesis (H_0) is proposed and either retained or rejected in favour of an alternative hypothesis (H_1).

6.2.1. Hypothesis I

H_0 - Archaeosediments from Middle Palaeolithic sites in Eastern Iberia do not preserve a microscopic and molecular record of Pleistocene climate conditions.

Several studies have highlighted the potential to trace climatic and environmental signals in soil micromorphological thin sections (Macphail et al., 2010; Macphail and Goldberg, 2018; Nicosia and Stoops, 2017; Nieuwendam et al., 2020; Vliet-Lanoë et al., 2004) and through compound-specific isotope analysis of sedimentary fossil leaf waxes (Diefendorf and Freimuth, 2017; Eley et al., 2016; Garcin et al., 2014; Ramos-Román et al., 2018; Yamamoto et al., 2010). However, most of these studies have focused on Holocene sediments or sites where organic preservation is generally good, limiting our understanding of how these signals might present in archaeosediments of Pleistocene age. The study sites investigated in this thesis, Abric del Pastor (MIS 5/4) and El Salt (MIS 3), are ideal for addressing these issues given their respective chronologies, the generally inorganic nature of their sediments, and their geographic setting in Eastern Iberia which experiences both Mediterranean and Atlantic climate influences. Data presented in chapter 3 and chapter 4 of this thesis demonstrate that sedimentary microstructures and fossil leaf waxes are preserved at Abric del Pastor and El Salt and responsive to dynamic external environmental and climatic processes.

128

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

The null hypothesis (H_0) is therefore rejected. The following alternative hypothesis (H_1) is proposed: **Archaeosediments from Middle Palaeolithic sites in Eastern Iberia do preserve a microscopic and molecular record of Pleistocene climate conditions.**

6.2.2. Hypothesis II

H_0 – **Combined microscopic and molecular analyses of sediments at the study sites do not allow accurate and precise reconstruction of past climatic and environmental conditions.**

Chapter 3 and chapter 4 combined archaeological soil micromorphology, lipid biomarker analyses of sedimentary fossil leaf waxes, and compound-specific isotope analyses to investigate past environmental and climatic conditions from Abric del Pastor and El Salt. In both cases, these techniques have been applied alongside other palaeoenvironmental proxies more traditionally employed in archaeology. Similar to other studies which used molecular and isotopic analyses of sedimentary lipid biomarkers in the Iberian Peninsula, we conclude changes in precipitation amount, temperature, local vegetation structure, water stress, and moisture source are the predominant drivers of molecular and isotopic changes (Schäfer et al., 2018; Schirrmacher et al., 2020; Toney et al., 2020). It is widely recognised that there are significant challenges disentangling these variables (Liu and An, 2018; Sachse et al., 2012), which is greatly exacerbated in older archaeological contexts where comparative climate records are typically more fragmentary. We have demonstrated in chapters 3 and 4 that soil micromorphology *can*, if somewhat tentatively, contribute supplementary information about the environmental and depositional context that can help to resolve this. At Abric del Pastor, cold climate conditions throughout the sequence are evidenced at the microstratigraphic level, and these conditions are corroborated in S.U. IVc and IVd through comparison with data from

the other palaeoenvironmental proxies. Given the site's chronology, this is also congruent with palaeoenvironmental data for the Iberian Peninsula based on marine sediment core datasets (Sánchez Goñi et al., 1999).

Soil micromorphology also highlighted likely changes in sedimentary rates at both Abric del Pastor and El Salt, which has significant implications for interpreting sedimentary lipid biomarker and compound-specific isotope results. Understanding changes in the mode or rate of sedimentation provide clues not only for understanding the duration of exposure of human occupation surfaces and activities which occurred thereon but critically, this technique helps reduce time-averaging or palimpsest effects and to characterise the sensitivity of the sedimentary environment to a range of relevant climatic and post-depositional variables (Bailey, 2007; Courty and Vallverdu, 2001). Furthermore, the experimental study we present in chapter 5 highlights the importance of identifying whether fine charred particles are present in sediments before sampling for lipid biomarkers. With this in mind, we propose that the combine application of soil micromorphology can contribute to more robust palaeoclimate reconstructions. The results presented in chapters 3 and 4 support the notion that sedimentary microscopic and molecular evidence from Abric del Pastor and El Salt reflect genuine Pleistocene climatic and environmental conditions, though these lines of evidence are no doubt enhanced by cross-validation with other palaeoenvironmental proxies.

The null hypothesis (H_0) is therefore rejected. The following alternative hypothesis (H_1) is proposed: **Combined microscopic and molecular analyses of sediments at the study sites do allow accurate and precise reconstruction of past climatic and environmental conditions.**

6.2.3. Hypothesis III

***H₀* – Sedimentary microscopic and molecular climate proxies cannot be usefully compared with traditional palaeoenvironmental proxies used in archaeological research.**

Chapters 3 and 4 provide useful case studies for exploring the ways that microscopic and molecular climate proxies can be compared with palaeoenvironmental data gleaned from the study of archaeological materials from the same sites, such as charcoal and faunal assemblages, as well as other sedimentary proxies such as microvertebrate remains and pollen/non-pollen palynomorphs. It is clear from the evidence presented in chapter 3 that practical and theoretical challenges exist linking palaeoenvironmental proxies which are responsive to climatic and environmental variables across different spatial and temporal scales. In practical terms, though our microscopic and molecular proxies cover the full sedimentary sequence at the site, the other proxy datasets are incomplete and could only be compared for S.U. IVd and, in the case of charcoal, also IVc. Also, we must consider that soil microstructures may reflect seasonal freeze-thaw processes, molecular and isotopic changes in fossil leaf waxes may be controlled by centennial to millennial-scale shifts in precipitation amount or North Atlantic Oscillation (NAO), the charcoal assemblage at the site is mostly if not totally the result of intermittent Neanderthal occupation activity and no doubt biased toward more favourable and available fuel sources. In contrast, the microvertebrate assemblage is linked to the Eurasian eagle-owl activities (*Bubo bubo*) whose range may extend beyond the limits of the ravine where the site is located. Emphasis on differences of scale, particularly concerning time, has been the focus of much discussion and debate in archaeology (Bailey, 2007, 1983; Holdaway and Wandsnider, 2008; Lucas, 2004). By combining climatic and environmental proxies which respond to different phenomena

and vary in terms of their respective spatial and temporal resolution, archaeologists will have the opportunity to address questions about relationships between different kinds of processes. The results presented in chapter 3 demonstrate that while inherent uncertainties may prevent direct correlations between individual datapoints from different proxies, broad relationships and inferences about regional environmental conditions can be discerned. Chapter 4 also reveals how our microscopic and molecular approach can complement other palaeoenvironmental proxies by overcoming issues surrounding preservation—for instance, sediment samples collected for pollen analysis from S.U. V (lower) at El Salt were found to be sterile, however, our lipid biomarker and compound-specific isotope results confirmed the regional presence of C3 vegetation during the deposition of this unit, while the presence of local vegetation cover in the immediate area around the site was evidenced by the occurrence of *Celtis sp.* seed coatings in our soil micromorphological samples.

The null hypothesis (H_0) is therefore rejected. The following alternative hypothesis (H_1) is proposed: **Sedimentary microscopic and molecular climate proxies can be usefully compared with traditional palaeoenvironmental proxies used in archaeological research.**

6.2.4. Hypothesis IV

H_0 – Sedimentary microscopic and molecular climate proxies do not indicate unstable environmental conditions during MIS 3 in Eastern Iberia.

It has been argued that MIS 3 was characterised by abrupt and unstable climatic changes marked by significant drops in temperatures and episodes of widespread aridification, producing environmental conditions and resource distributions not typically found in modern environments (Stewart, 2005). At a global and continental scale, this

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

climatic instability has been recorded by several different proxies, including $\delta^{18}\text{O}$ of Greenland ice-cores (NGRIP), evidence of ice-rafted debris (IRD) from North Atlantic marine sediment cores, and isotope records of planktonic and benthic foraminifera, among other sources (Adams et al., 1999; Birner et al., 2016; Blockley et al., 2014; Maslin et al., 2013; North Greenland Ice Core Project members, 2004; Rasmussen et al., 2014; Sánchez Goñi et al., 2008). This has led many researchers to implicate climatic crises during MIS 3 in Neanderthal demise in the Iberian Peninsula (Finlayson, 2004; Finlayson and Carrión, 2007; Jiménez-Espejo et al., 2007; Müller et al., 2011; Wolf et al., 2018). As set out in chapter 1, however, it is unclear the extent to which reconstructions based on coarse proxies such as these reflect conditions at a regional scale. Given the large error range in the available MIS 3 chronometric dates from the study sites investigated in this thesis, attempts to link our microscopic and lipid molecular records with larger climate datasets remain speculative. Nevertheless, the results from both sites demonstrate millennial scale climatic variability throughout MIS 3. This variability is particularly pronounced at El Salt in the observed fluctuations in *n*-alkane molecular ratios such as CPI, ACL, and VPD, as well as in compound-specific carbon and hydrogen isotope values. The formation of phosphatic crusts, observed in our micromorphological samples, are also interpreted as evidence of intermittent surface stabilisation linked to broad changes in regional environmental conditions and vegetation structure.

The null hypothesis (H_0) is therefore rejected. The following alternative hypothesis (H_1) is proposed: **Sedimentary microscopic and molecular climate proxies *do* indicate unstable environmental conditions during MIS 3 in Eastern Iberia.**

6.2.5. Hypothesis V

H_0 – There is *no* consistent relationship between climate change or abrupt climate events and Neanderthal activity at the selected study sites.

Global cooling during MIS 4, climatic instability and rapid ecological turnover during MIS 3, and abrupt climate events such as HE 5 (c. 50 - 47 kya) and HE 4 (c. 39 kya) have long been implicated in the demise of Neanderthal populations in the Iberian Peninsula (Finlayson, 2004; Finlayson and Carrión, 2007; Mallol et al., 2019; Mellars, 2006; Müller et al., 2011; Sepulchre et al., 2007). In chapter 3 and chapter 4 of this thesis, we have provided new lines of evidence for investigating the relationship between Neanderthal occupations in the Alcoy region of Eastern Iberia and fluctuations in environmental conditions through the course of MIS 4 and MIS 3. The results of our multiproxy study presented in chapter 3 indicate regional climatic and environmental fluctuations through the sedimentary sequence at Abric del Pastor, despite which there is abundant evidence for repeated short-term Neanderthal occupation events dated between 48 kya \pm 5 (MIS 3) and 62 kya \pm 12 (MIS 4). Recent technical and spatial studies of lithic refits from S.U. IV (IVb, IVc, IVd) at the site indicate a minimum of 9 distinct Neanderthal occupation episodes, represented by broadly similar hearth-related assemblages (Machado et al., 2019, 2013). Although the overall number of occupation events is too low to meaningfully discern causal or correlative relationships between the palaeoenvironmental and archaeological records, it is notable that the most intense occupation activity is recorded in S.U. IVd, which is dated by OSL to 63 kya \pm 5. This may be pronounced by palimpsest effects due to a slowing down in the rates of sedimentation at this part of the sequence, as indicated by our soil micromorphology samples. Alternatively, this may reflect a real, if somewhat modest, increase in human

María de las Maravillas Aguiar Aguiar UNIVERSIDAD DE LA LAGUNA	19/03/2021 14:28:17

occupation of the rock shelter linked to a downturn in wider regional environmental conditions.

It is also noteworthy that the last chronometric dates for Neanderthal activity at Abric del Pastor, 48 kya \pm 5 (S.U. IVb), overlap with the dates from the nearby site of El Salt where the final Neanderthal occupations are recorded c. 45 kya (Galván et al., 2014). There, our palaeoenvironmental results point to unstable environmental conditions in S.U. VIII - VI, with turnover in local vegetation structure linked to episodic fluctuations in humidity and intermittent periods of soil surface stabilisation. During this time, evidence for Neanderthal occupation activities is abundant both at the microscopic scale through soil micromorphology and at the macroscopic scale of excavation. However, our results reveal that the final Neanderthal occupations at El Salt are coincident with an abrupt change in sedimentary dynamics recorded in S.U. V and the onset of regional aridification following HE 5 but prior to the commencement of HE 4, in line with previous studies from this site and elsewhere (Fagoaga et al., 2019; Galván et al., 2014; Kehl et al., 2013; Wood et al., 2013).

The palaeoclimate and palaeoenvironmental records for both Abric del Pastor and El Salt exhibit high variability. Despite evidence for aridification at El Salt around the time of the final Neanderthal occupations, and the disappearance of Neanderthals from Abric del Pastor around the same time, the evidence presented in this thesis does not provide sufficient grounds in and of itself to support arguments in favour of a consistent relationship between climate change or abrupt climate events and Neanderthal activity at the selected study sites. The evidence presented here certainly does not preclude such relationships, or otherwise suggest that Neanderthal activity at the sites is unconnected to climatic processes. However, there are confounding differences in resolution and completeness between archaeological and palaeoclimatic datasets that demand further

evidence to meaningfully link local environmental conditions and Neanderthal social and cultural processes through time.

The null hypothesis (H_0) is therefore retained.

6.3. Conclusion

The work presented in this thesis has highlighted the applicability and potential value of systematically combining archaeological soil micromorphology and compound-specific isotope analysis of sedimentary lipid biomarkers for reconstructing palaeoenvironmental conditions from well-described archaeological contexts and providing new lines of evidence for investigating the relationship between past peoples and their environments. The results presented here have also added new levels of detail to our understanding of the regional palaeoclimatic and environmental variability of MIS 4 through MIS 3, which framed the disappearance of Neanderthals in the Alcoy region of Eastern Iberia. Combined microscopic and molecular approaches such as this present an opportunity to not only enhance existing onsite palaeoenvironmental records but crucially, to reconstruct conditions even in archaeological contexts where post-depositional disturbance or poor preservation renders other proxies such as charcoal or pollen obsolete. Chapter 1 argued reconstructions based on ice-core and deep-sea sediments, or discontinuous terrestrial palynological sequences, lack the spatio-temporal resolution to meaningfully investigate the role of climate in Neanderthal social and cultural evolution at a regional scale. As demonstrated in chapter 3 and chapter 4, regional and local variability is an important feature of Abric del Pastor and El Salt's palaeoenvironmental records. Despite our microscopic and molecular approach, there are still significant challenges linking palaeoenvironmental and archaeological records due to spatial or temporal resolution differences and inherent chronological uncertainties.

It is anticipated that archaeological soil micromorphology and compound-specific isotope analysis of lipid biomarkers will increasingly be utilised to investigate archaeosediments to elucidate links between past climate changes and trends in human cultural evolution. Based on this thesis's results, the combined future application of these techniques should focus on integrating methods or approaches for establishing improved chronologies and spatial resolution. To this end, researchers will no doubt benefit from recent advances in Bayesian statistical analysis of high-precision radiocarbon dates, as well as recent breakthroughs in compound-specific radiocarbon analysis (CSRA) of individual lipid compounds (Casanova et al., 2020; Deviese et al., 2018; Smyth et al., 2019). Recent research has also revealed exciting possibilities for targeted molecular and isotopic analysis of lipid biomarkers from polyester resin-impregnated soil micromorphology sediment slabs (Rodríguez de Vera et al., 2020). Future work that combines these advances with the approach set out in this thesis has the potential to provide unprecedentedly detailed reconstructions of regional and local climatic variability from onsite records and facilitate robust explorations of links between palaeoenvironmental and archaeological records. Developments in this direction will offer exciting new avenues for investigating the complex mechanisms that underpin how past societies responded to environmental or climatic changes, helping researchers gain a more nuanced understanding of the role of climate in Neanderthal social and cultural evolution.

Chapter 3: Material and methods (extended)

Dosimetry on site

10 Al₂O₃:C dosimeters were inserted (S.U. I to VI) and remained in place for a duration of five months. Doses were measured following Kreutzer et al. (2018). Obtained dose rates (gamma + cosmic) are low and do not show significant variation through the stratigraphic sequence (from 317 to 388 µGy/a). This likely corresponds with the calcareous nature of the sediments. These external dose rates were used for calculating the ages of both the tooth and sediment samples.

Dated sediment samples

Sediment was collected from S.U. IVd in absolute darkness and dated using Optically Stimulated Luminescence (OSL). Quartz grains (60-80µm) were extracted by sieving and subsequently purified using acids (HCl and H₂SiF₆). The Single Aliquot Regenerative (SAR) dose protocol (Wintle and Murray, 2000) was applied to large aliquots (6mm in diameter) for measuring the fast component of the OSL signal. A preheating plateau test was carried out, which indicated no dependence of the equivalent doses (De) on temperature (200 - 260°C). Following this, a dose recovery test was conducted and yielded a value close to one (1.02 ± 0.02). A series of 20 aliquots were then analysed and the representative De was calculated using the Central Age Model (Galbraith et al., 1999). Determination of U, Th, K contents in the sediment was carried out by gamma spectrometric analysis, allowing for the alpha and beta external dose rates received by the 60-80µm grains to be calculated.

Dated Teeth

Two herbivore teeth were selected for combined ESR / U-series dating. An Equidae premolar recovered from S.U. IVb (sample AP1601) and a Bovinae tooth recovered from S.U. VI (sample AP1602). Enamel, dentin and cement in AP1601 were separated mechanically. Alpha-ray spectrometry was used to measure the radio-isotope content in the dentin and cement following standard methods (Bischoff et al., 1988), and by gamma-ray spectrometry (Yokoyama, and Nguyen, 1980). Analysis was carried out at the Institut de Paléontologie Humaine (IPH), Paris.

ESR measurements were carried out using an EMX Bruker ESR spectrometer applying the following parameters: 1mW microwave power, 0.1mT modulation amplitude, room temperature (19°C), 10mT scan range, 4min scan time and 100kHz frequency modulation. A minimum of three measurements was recorded for each dose on different days. The equivalent doses (DE) were determined from the asymmetric enamel T1-B2 signal at $g = 2.001853$ and fitted from the experimental data using an exponential function (SSE) with Microcal Origin Pro 8 software with $1/I^2$ weighting. The DE were calculated from mean values obtained from three repeated measurements for each aliquot. ESR age calculations were achieved using the ESR-DATA program (Grün, 2009), which utilises an alpha efficiency of 0.13 ± 0.02 (Grün and Katzenberger-Apel, 1994) and Monte-Carlo beta attenuation factors (Brennan et al., 1997) determined by the thickness of the tooth enamel and outer layers removed. The analysis was carried out at the Institut de Paléontologie Humaine (IPH), Paris.

Microvertebrate study (IVd)

The minimum number of individuals (MNI) was calculated to establish the abundance of each species in the fossil assemblage. In order to reconstruct the palaeoenvironmental

context of S.U. IVd from Abric del Pastor, the Habitat Weighting method developed by Whittaker (1948), Rowe (1956) and Gauch (1989) was employed. This procedure consists of defining a value, in a range between 0 and 1, for each species in each habitat where it is found. Following Cuenca-Bescós et al. (2005), the habitats considered in this work are: Open dry (OD), meadows under seasonal climate change; Open humid (OH), evergreen meadows with dense pastures and suitable topsoil; Woodland (W), mature forest; Open Woodlands (OWo), woodland margins and forest patches, with moderate ground cover; Rocky (R), areas with a suitable rocky or stone substratum and Water (Wa), areas along streams, lakes and ponds. The ecological preferences of the different taxa described in the present work have been taken from Pleguezuelos et al. (2002), Palomo et al. (2007), Bencatel et al. (2017) and López and Martín (2018).

Prior to palaeoclimatic and palaeoenvironmental interpretation it is necessary to conduct a taphonomic study to identify predator(s) species responsible for the small mammal assemblage (e.g. Andrews, 1990; Vigne and Valladas, 1996; Pokines, 2000). Predation is the main factor involved in the accumulation of small mammal assemblages (Dodson and Wexlar, 1979; Korth, 1979; Andrews and Evans, 1983; Andrews, 1990; Kusmer, 1990; Stahl, 1996 amongst others) and it can be recognised by the presence of fossil digested remains (Raczyński and Ruprecht, 1974; Mellet, 1974; Mayhew, 1977; Andrews, 1990; Fernández-Jalvo and Andrews, 1992; Lloveras et al., 2014; Fernández-Jalvo et al., 2016). In this preliminary taphonomic study, the degree and frequency of digestive corrosion on both bones and dental elements have been examined. For the identification of the source of taphonomic information we used the criteria provided by Andrews (1990), Fernández-Jalvo and Andrews (1992) and Fernández-Jalvo et al. (2016).

Macrofaunal study (IVd) - Material and methods (extended)

All remains were analysed taphonomically using macroscopic and microscopic techniques (Leuchtturm hand lens up to 20x and Leica M165C stereo light, magnification ranging from 10x to 120x) to identify biostratigraphic and diagenetic modifications. In the fracture analysis, we classified all of the fragments by fracture type following the criteria established by Villa and Mahieu (1991) and the morphotypes created by Real (2012; 2016). All dimensions were measured for each bone fragment. Bone surface modifications were observed and quantified to identify damage caused by anthropogenic activity (thermal alteration, percussion and butchering marks) or predator damage (tooth marks, digestion), as well as the diverse diagenetic processes that produce alterations on bone surfaces (erosion, sediment concreteness, roots marks, weathering, pigmentation, trampling) (Binford, 1981; Shipman, 1981; Shipman and Rose, 1983; Lyman, 1994; Reitz and Wing, 2008; Domínguez Rodrigo and Yravedra, 2009; Denys and Patou-Mathis, 2014; Fernandez-Jalvo and Andrews, 2016).

Taphonomic remarks on the microfaunal assemblage

Evidence of digestion damage is detected in cranial and postcranial elements indicating that the fossil assemblage is produced by predation. The total percentage of digested incisors is close to 31% while in molars it is around 19%. The most frequent degree of digestion observed is light followed by moderate. Samples with a heavy degree of digestion were scarce and only detected in molars. No evidence of extreme degree was observed either on molars or on incisors. Digestion of long bones on proximal ends of femurs and distal ends of humeri affects 38% and 36% of the assemblage, respectively. Based on the overall results, the evidence from S.U. IVd at Abric del Pastor points to category 3 digestion (Andrews, 1990; Fernández-Jalvo and Andrews, 1992; Fernández-Jalvo et al., 2016) in which the Eurasian eagle-owl (*Bubo bubo*) and the tawny owl (*Strix aluco*) are the most probable predators. Both predators fall under “intermediate modification” according to Andrews (1990), although *Bubo bubo* may fit better with data obtained from Abric del Pastor for the present study.

Taphonomic data and anthropogenic alterations - macrofaunal assemblage

Regarding surface features informative of anthropogenic activities, anthropogenic marks are sparse. They were identified on 26 bones or fragments (5.4% NR). Slicing marks and notches prevail, followed by scraping marks and a few cases of crenulated edges and peeling (Table 4). These features are concentrated on bones of *Capra pyrenaica*, *Cervus elaphus*, *Testudo hermanni* and medium-weight animals. Nevertheless, the distribution and nature of the marks suggest on-site butchering activity, including disarticulation, evisceration, defleshing, periosteum removal, percussion, and flexion. Thermally altered bone remains are common (14.7% NISP), particularly Mediterranean tortoises and undetermined bone fragments. These mainly exhibit incipient alteration and carbonisation

(200-400°C), although some are strongly burned and calcined (600-700°C). None of the remains shows burning over the entire surface. In the tortoise, thermal alteration is present mainly on the exterior face of plates. This relates to cooking practices and has been demonstrated in others works from Abric del Pastor (Sanchis et al., 2015), Gruta da Figueira Brava and Gruta da Oliveira (Nabais and Zilhão, 2019). Finally, lagomorphs, carnivores and birds within the assemblage do not appear to be associated with human activity, based on the absence of anthropogenic features.
